ABSTRACT

5871016063: Petrochemical Technology Program
Ratchawan Jarumanee: Study on Energy Storage Ability of
ZnO/TiO₂ for Photocatalytic Degradation of Isopropanol.
Thesis Advisors: Prof. Pramoch Rangsunvigit, and Asst. Prof. Pailin
Ngaotrakanwiwat 84 pp.

Keywords: Photocatalytic degradation/ Photocatalyst/ TiO₂/ Isopropanol/
Energy storage

The photocatalytic degradation of isopropanol under UV irradiation was studied by using p-n junction of ZnO/TiO₂ photocatalysts prepared by sol-gel technique. Their energy storage ability was tested with their photocatalytic activity where there was no UV illumination. That was investigated by illumination the system with UV light for 2 h and off for 2 h until 8 h. The composition and surface structure of the catalyst were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), surface area analysis, and particle size analysis. The change in the isopropanol concentration was observed by using gas chromatography. The result showed that the degradation efficiency of the ZnO doped on TiO₂ layer films was higher than the single-TiO₂ thin film, about 74.0% and 48.0%, respectively. Moreover, acetone was found during the photocatalytic degradation process of isopropanol. The effects of isopropanol solution pH, ZnO loading, and ZnO calcination temperature were studied. ZnO calcined at 600°C and 15 mol% at unadjusted pH was suitable for both photocatalytic activity and energy storage. The photocatalytic degradation rates of isopropanol for the first and second illumination were about 21.0% and 20.8%, respectively. With no illumination, the highest degradation of isopropanol was about 14.8%.

ACKNOWLEDGEMENTS

I would like to express my sincere thanks to my thesis advisor, Prof. Pramoch Rangsunvigit, for his invaluable help and constant encouragement throughout the course of this research. I am most grateful for his discussions and advices. I would not have achieved this far and this thesis would not have been completed without all support that I have always received from him.

I would like to thank my co-advisors, Asst. Prof. Pailin Ngaotrakanwivat for suggestions, guidances, and all their helps.

I would also like to thank to the thesis committees, Assoc. Prof. Siriporn Jongpatiwut and Assoc. Prof. Paisan Kongkachuichay.

In addition, I would like to thank the entire faculty and staff at the Petroleum and petrochemical College, Chulalongkorn University and Department of Chemical Engineering, Burapha University for their kind assistance and cooperation.

Unforgettably, I am grateful for the partial scholarship and partial funding of the thesis work provided by the Petroleum and Petrochemical College, and the Center of Excellence on Petrochemical and Materials Technology, Thailand. And this research was partially supported by The 90th Anniversary of Chulalongkorn University Fund (Ratchadaphiseksomphot Endowment Fund), Chulalongkorn University, Thailand and National Research Council of Thailand.

Finally, I most gratefully acknowledge my parents and my friends for all their support throughout the period of this research.

CHAPTER I

INTRODUCTION

In recent years, development of industries especially semiconductor manufacturing and other high-tech electronic industries are enlarged, and these industries are connected with discarding of a vast number of organic pollutants, which are harmful to microbes, aquatic system, and human health (Tian *et al.*, 2009). Isopropanol is a commonly used in solvent semiconductor industry and present at high concentrations in wastewater. Wastewater containing organic solvent that is not decomposed deteriorates the quality of water in the environment, while its volatile nature results in air pollution that affects the health of factory workers and residents in the neighborhood. Moreover, isopropanol and its metabolite, acetone, act as central nervous system depressants (Burkhart and Kulig, 1990).

Many methodologies have been applied in the treatment of organic compounds such as biological treatment, reverse osmosis, ozonation, filtration, adsorption on solid phases, incineration, and coagulation (Garcia *et al.*, 2008). However, each of them has its own limitations; deadly toxic volatiles products (Vinita *et al.*, 2010), ghastly smell, quite expensive, and do not eliminate the organic compounds utterly but just transform one phase to another (Zelmanov and Semiat, 2008). In recent era, photocatalytic oxidation/degradation process has been found as an effective and alternative way for treatment of the organic compounds (Huang *et al.*, 2008). Several studies have used this technique to chemically convert isopropanol into nontoxic compounds such as water (H₂O) and carbon dioxide (CO₂) (Zhao and Yang, 2003).

Among the photocatalysts, titanium dioxide (TiO₂) has been attracted for the degradation of environmental contaminants because of remarkable photocatalytic activity, non-toxicity, low cost, and good chemical stability (Pelaez *et al.*, 2012). However, the uses of TiO₂ as a photocatalyst have some limitations, which are the recombination of photo-generated charged carriers; therefore, some researchers have attempted to modify TiO₂ by doping it with metals/metal oxide loading (Adriana, 2008). Furthermore, TiO₂ functions only under light irradiation that cannot be applied for indoor air and water purification. To overcome these limitations, researchers have developed photocatalysts with energy storage abilities. The oxidation energy storage has

been reported by p-n junction concept, which utilizes the contact between a p-type semiconductor such as Ni(OH)₂, Cu₂O, V₂O₅ with TiO₂ as a redox-active n-type semiconductor. The oxidative energy of photocatalysts is stored in a p-type semiconductor, and it is possible to retain the removal of some toxic compounds without illumination. Takahashi and Tatsuma (2005) revealed that the stored oxidative energy can be discharged electrochemically or used for chemical oxidation of various species. Xiong *et al.* (2009) and similar work carried out by Yamasonee and Bandara (2008) reported that the system may be potentially applied to portable devices charged at daytime and used at night without extra storage cells. A photocatalyst with reductive energy storage ability has been developed by doping TiO₂ as an n-type semiconductor with a redox active n-type such as WO₃, MoO₃ or H₃PW₁₂O₄₀ (phosphotungstic acid; PWA). The reductive energy of photocatalysts is stored in an n-type semiconductor, and it utilizes to keep anti-corrosion and bactericidal effects in the dark. Tatsuma *et al.* (2002) revealed that the reductive energy can be stored by WO₃, and the reductive energy can be retained for a certain period even after the light was turned off. Takahashi *et al.* (2003) suggested that MoO₃ exhibited larger charging and discharging capacities and greater ability for oxygen reduction than did WO₃, and it might be used as bactericidal materials under humid conditions. However, TiO₂ is an n-type semiconductor, in which the electrons in its conduction band are mobile, whereas the holes in its valence band are much less mobile, so that the storage of the oxidative energy of TiO₂ should be more difficult than that of the reductive energy. Hence, the oxidative energy storage has been challenging in recent years.

Chavadej *et al.* (2008) studied photocatalytic degradation of isopropanol by using Pt/TiO₂ as a photocatalyst. They reported that the photodegradation activity of TiO₂ doped with platinum was better than using titania or platinum alone. Apart from that, the photocatalytic activity of TiO₂ was improved by a metal dopant such as V, Fe, Cr, and Pt. Moreover, they found that acetone was detected as an intermediate product. Yamashita *et al.* (2001) also suggested that the contact between the n-type TiO₂ and the p-type doped TiO₂ introduced the p-n junction that drove electron and hole. Shifu *et al.* (2008) studied photocatalytic activity of p-ZnO/n-TiO₂ that is similar to other works by Giuseppe *et al.* (2001) and Ming *et al.* (2009). These studies revealed that, when the p-type ZnO and n-type TiO₂ were integrated, a p-n junction was formed. At equilibrium,

inner electric field made the p-type semiconductor ZnO region to have negative charge, while the TiO₂ region had positive charge. Under near UV illumination, electron-hole pairs may be created, and the photogenerated electron-hole pairs are separated. The holes flowed into the ZnO region, while the electrons moved to the TiO₂ region. As a result, the separation of electron-hole pairs was efficiently generated leading to the enhancement of photocatalytic activity.

As mentioned previously, it is important to understand how this p-n junction concept can reserve energy. Therefore, the main goal of this research is to prepare a p-n junction of TiO₂ as an n-type semiconductor with ZnO as a p-type semiconductor by sol-gel method. Moreover, the photodegradation of isopropanol by using ZnO/TiO₂ as the oxidative energy storage photocatalyst with and without UV illumination, and intermediate product of isopropanol photodegradation will be investigated.

CHAPTER II

THEORETICAL BACKGROUND AND LITERATURE REVIEW

2.1 Principle of Photocatalysis

Photocatalysis is a technical term conventionally defined as “the acceleration of the rate of a chemical reaction, induced by the absorption of light by a catalyst or co-existing molecule” (Serpone and Salinaro, 1999; Braslavsky, 2007). Basic photochemical principles of heterogeneous photocatalysis have been reported in many literatures and found that organic molecules came into contact with a catalyst surface under irradiation, inducing a series of oxidation and reduction (redox) reactions and degrading pollutant molecules (Ohtani, 2014). The heterogeneous photocatalysis is a discipline, which includes a large variety of reactions: organic synthesis, water splitting, photoreduction, hydrogen transfer, $O_2^{18}-O_2^{16}$ and deuterium-alkane isotopic exchange, metal deposition, etc. (Gaya and Abdullah, 2008). These different reactions are related with many applications, air and water treatment, active surfaces, green chemistry, and energy conversion (Coronado *et al.*, 2008). Normally, it is accepted that the degradation of pollutants consists of many kinds of reaction after illumination of semiconductor particles (Kisch, 2013).

Semiconductor heterogeneous photocatalysis has enormous potential to treat organic contaminants in water and air. This process is known as advanced oxidation process (AOP) and is suitable for the oxidation of a wide range of organic compounds. Basically, when light is absorbed by a semiconductor photocatalyst, electronic excitations take place, which can be exploited in chemical or electrical work. The material absorbs light when the energy of incident photons is equal or larger than band gap energy of the semiconductor. Thus, an electron is excited from valence band (VB) into its conduction band (CB) and leaving hole behind (Roland, 2014). The schematic representation of semiconductor energy band is shown in Figure 2.1.

Figure 2.1 Schematic representation of semiconductor energy band (Angelo *et al.*, 2013).

The semiconductor energy band consists of valence band (E_{VB}) and conduction band (E_{CB}). The energy difference between the conduction and valence edges is called the band gap energy of the semiconductor (E_{BG}).

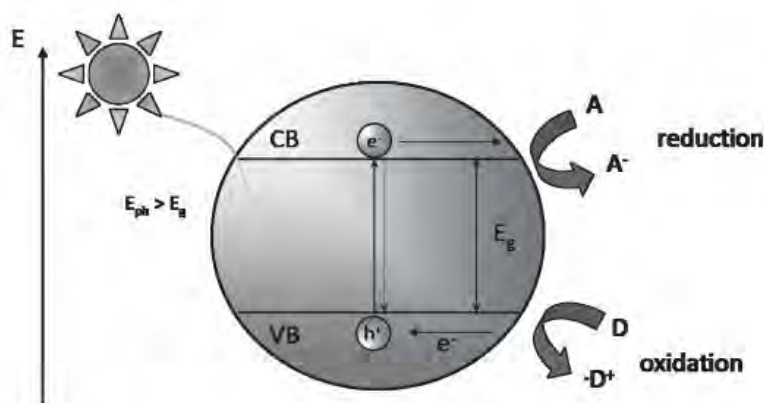

Figure 2.2 Basic processes of charge carrier generation upon the light irradiation of a semiconductor particle; E_{ph} : energy of irradiated photon, A: electron acceptor, D: electron donor. (Roland, 2014).

The basic three steps of photocatalytic reactions are 1) photoexcitation of charge carriers; 2) charge carrier separation and diffusion to the photocatalyst surface; and 3) oxidation and reduction reaction on the catalyst surface. During step (2), recombination can occur via different mechanism. The major pathway is already

mentioned relaxation of photoexcited electrons back to the valence band, which can directly happen from the conduction band. For example, if the photogenerated charge carriers are not used in photocatalytic reactions, they will recombine. The basic principles of these processes are depicted in Figure 2.2 (Roland, 2014).

In the photocatalyst reaction, redox potential of photogenerated valence band hole must be sufficiently positive to generate OH^\bullet radicals, which can subsequently oxidize the organic pollutant followed by Eq. (2.1)

Photocatalytic degradation (PCD) process is gaining importance in the area of wastewater treatment; especially for wastewater containing small amounts of refractory organic substances. The process has several advantages over competing processes. There are: (1) complete mineralization, (2) no waste disposal problem, (3) low cost, and (4) only mild temperature and pressure conditions are necessary (Mills *et al.*, 1993).

Figure 2.3 Schematic diagram of photocatalytic degradation of organic effluent (Gnanaprakasam *et al.*, 2015).

As mentioned previously, the photocatalytic degradation involves several steps such as adsorption-desorption, electron-hole pair production, recombination of electron pair, and chemical reaction. The general mechanism of photocatalytic degradation of organic molecules is explained in Figure 2.3.

When the photocatalyst is irradiated with photon of energy equal to or more than its band gap energy, generation of excited high-energy states of electron and hole pairs occurs. It results in the promotion of an electron in the conduction band (e^-_{cb}) and formation of a positive hole in the valence band (h^+_{vb}), as shown in Eq. (2.2).

where $h\nu$ is the energy essential to transfer the electron from valence band to conduction band. The e^-_{cb} and h^+_{vb} are powerful oxidizing and reducing agents, respectively. Both of them can migrate to catalyst surface, where they can enter in a redox reaction with other species present on the surface. The electrons generated through irradiation could be readily trapped by O_2 absorbed on the photocatalyst surface or dissolved O_2 to give superoxide radicals ($O_2^{\cdot-}$), as shown in Eq. (2.3).

Consequently, $O_2^{\cdot-}$ could react with H_2O to produce hydroperoxy radical (HO_2^{\cdot}) and hydroxyl radical (OH^{\cdot}), which are strong oxidizing agents to decompose the organic molecule, as shown in Eq. (2.4).

Simultaneously, the photoinduced hole could be trapped by surface hydroxyl group (or H_2O) on the photocatalyst surface to give hydroxyl radicals (OH^{\cdot}), as shown in Eq. (2.5).

Finally, the organic molecules will be oxidized to yield carbon dioxide and water by reacting with hydroxyl radical (OH \cdot) due to its electrophilic nature (electron preferring), the OH \cdot can non-selectively oxidize almost all electron rich organic molecules as follows:

Meanwhile, recombination of positive hole and electron could take place which could reduce the photocatalytic activity as follows: (Gnanaprakasam *et al.*, 2015)

Bhatkhande *et al.* (2001) reviewed the chemical effects of various variables on the rate of degradation of different pollutants. They discussed that effect of operation parameters, which could influence the photocatalytic degradation of organic pollutants, such as adsorption, intensity of light, pH, temperature, and presence of anions, cations. Effects of adsorption also were analyzed, and it was concluded that the substances, which were readily adsorbed, were degraded at a faster rate, indicating that the reaction was a surface phenomenon. And the effects of pH was negligible so pH adjustment was not required. They suggested that a light source and catalyst also affected the cost of the operation. Solar radiation was obviously an attractive proposition.

Zhao *et al.* (2005) reviewed progress in the TiO₂ photocatalytic degradation of organic pollutants by visible light. They focused on metal semiconductor, which operates at ambient conditions. Under such conditions, the dyes not only are decolorized, but also mineralized. As the TiO₂ semiconductor is relatively large band gap and can be excited only by high energy UV radiation, extending the response of TiO₂-based material to the visible region can be achieved in many ways such as dye sensitization,

non-metal or transition metal ions doping, and surface modification. However, the removal efficiency of organic pollutants from water or air in visible region is low.

Akpan and Hameed (2009) reviewed the effect of operating parameters including pH, oxidizing agents, and catalyst loading on the photocatalytic degradation of textile dyes, dopant content, and calcination temperature by using TiO₂-based photocatalysts. The finding revealed the various operational parameters affected the effectiveness or activities of TiO₂-based photocatalysts. The reaction should be undertaken at the proper pH. Oxidizing agents, calcination temperature, and catalyst loadings were found to exert their individual influence on the photocatalytic degradation of any dyes. And it was also discovered that the sol-gel method was widely used.

Umar and Aziz (2013) reviewed the degradation of organic pollutants in water by using semiconducting oxide photocatalysts. The process is capable of removing a wide range of organic pollutants such as pesticides, herbicides, and micropollutant such as endocrine disrupting compounds. Especially, the TiO₂ has been most commonly because of its ability to break down organic pollutants and even complete mineralization. However, this application is constrained such as wide band gap (3.2 eV), lack and inability for high proton efficiency to utilize wider solar spectra. And they suggested that the use of solar radiation has to be improved by virtue of the design of the photoreactor in order to reduce the cost of treatment.

2.2 Titanium Dioxide (TiO₂)

Titanium dioxide (TiO₂) is a material with a huge technological relevance because of its numerous applications (e.g. pigments, sensors, catalyst). Strong oxidation and reduction power of photoexcited TiO₂ was realized from the discovery of Honda-Fujishima effect in 1972, who reported photoinduced decomposition of water by solar light on TiO₂ electrodes. Thus, this solid has been attracting the interest of the scientific community mainly and remaining as the most widely used photocatalyst. In fact, this oxide has been considered as a synonym of photocatalyst, because more than 67% of the articles about photocatalysis are still based on the use of TiO₂. The reasons for this prominent position of TiO₂ as a photoactive material rely

mainly on its particular physicochemical characteristics, thermally stable, non-toxic, optical and electrical properties, and capable of promoting oxidation of organic compounds, although other aspects, like its biocompatibility and its availability at a relatively low cost, have also facilitated the extensive use of this semiconductor (Coronado *et al.*, 2008).

Photocatalytic reactions at the surface of TiO_2 have been attracting much attention in view of their practical applications to environmental cleaning such as self-cleaning of tiles, glasses, and windows. The TiO_2 represents an effective photocatalyst for water and air purification and for self-cleaning surfaces. Additionally, it can be used as antibacterial agent because of strong activity and superhydrophilicity (Fujishima and Zhang, 2006).

2.2.1 Structure of Titanium Dioxide

Figure 2.4 Schematic conventional cells for anatase (a), rutile (b) and brookite (c). The big green spheres represent Ti atoms and the small red spheres represent O atoms (Zhang *et al.*, 2007).

Titanium dioxide (TiO₂) or titania exists in four mineral forms, viz: anatase, rutile, brookite, and metastable TiO₂ or TiO₂ (B) that can be prepared without using special synthesis conditions (Gianluca *et al.*, 2008). Anatase type TiO₂ has a crystalline structure that corresponds to the tetragonal system (with dipyramidal habit) and is used mainly as a photocatalyst under UV irradiation. Rutile type TiO₂ also has a tetragonal crystal structure (with prismatic habit). This type of titania is mainly used as white pigment in paint. As the different arrangements, rutile is denser (4.250 cm³.g⁻¹) than anatase (3.894 cm³.g⁻¹). In case of brookite type, TiO₂ has an orthorhombic crystalline structure. It consists of chains of edge-sharing octahedra connected to each other by vertices. This type of TiO₂ is closely related to that of anatase, but it presents a different array of octahedral chains, which results in less dense crystals, so it is not often used for experimental investigations (Chen and Mao, 2007). These three crystal structures are represented in Figure 2.4. And TiO₂ (B) is a monoclinic mineral and is a versatile material that has applications in various products such as paint pigment, sunscreen lotions, electrochemical electrodes, capacitors, solar cells, and even food coloring agent, and in toothpastes (Meacock *et al.*, 1997). Only rutile and anatase will be focused because both of them are inexpensive, chemically stable, harmless and photocatalytic application (Lan *et al.*, 2013).

2.2.2 Photocatalytic Degradation Mechanism of Titanium Dioxide

Due to TiO₂ shows relatively high reactivity and chemical stability under ultraviolet light ($\lambda < 387$ nm), whose energy exceeds the band gap of 3.2 eV in the crystalline phase, so it has been the most studied semiconductor for photocatalytic applications (Adriana, 2008).

In the basic mechanism, photocatalysis reaction is activated by absorption of a photon with sufficient energy by equal to or higher than 3.2 eV resulting in initiating excitation related to charge separation event (gap band). It results in the promotion of an electron from the valence band to the conduction band, thus generating hole in the valence band. The ultimate goal of the process is to have a reaction between the activated electrons with an oxidant to produce an oxidized product. The photogenerated electrons could reduce the dye or react with electron acceptors such as O₂ adsorbed on the Ti(III)-surface or dissolved in water, reducing it

to superoxide radical anion ($O_2^{\bullet -}$). The photogenerated holes can oxidize the organic molecule (R) to form R^+ , or react with OH^- or H_2O oxidizing them into OH^\bullet radicals. Together with other highly oxidant species (peroxide radicals), they are reported to be responsible for the heterogeneous TiO_2 photodecomposition of organic substrates as dyes. The resulting OH^\bullet radicals, being a very strong oxidizing agent (standard redox potential +2.8 eV) can oxidize most azo dyes, electron poor aromatics, or quinones to the mineral end-products. According to this, the relevant reactions at the semiconductor surface causing the degradation of organic molecules can be expressed as follows (Konstantinou and Albanis, 2004):

The presence of dissolved oxygen is extremely important during photocatalytic degradation as it can make the recombination process on TiO_2 (e^-_{cb}/h^+_{vb}) difficult, which results in maintaining the electroneutrality of the TiO_2 particles (Boroski *et al.*, 2009). In other words, it is important for effective photocatalytic degradation of organic pollutants that the reduction process of oxygen and the oxidation of pollutant proceed simultaneously to avoid the accumulation of electron in the conduction band and thus reduce the rate of recombination of e^-_{cb} and h^+_{vb} (Hoffmann *et al.*, 1995).

2.2.3 Doping of Titanium Dioxide

Figure 2.5 Modification of titania photocatalyst by using metal doping (Gaya and Abdullah, 2008).

Doping of photocatalyst could improve the photocatalyst efficiency in the following ways: (1) band gap energy narrowing (Sathishkumar *et al.*, 2013); (2) formation impurity energy levels (Cao *et al.*, 2013); (3) oxygen vacancies; (4) unique surface are for the adsorption of organic molecules (Wu *et al.*, 2010); and (5) electron trapping (Barakat *et al.*, 2013). In general, catalyst with smaller band gap energy is preferred to be an effective photocatalyst to generate more electron hole pairs. Band gap narrowing, introduction of impurity energy level, and oxygen-deficient sites can result in a catalyst with higher photocatalytic activity even under visible light. Thus, doping prevents recombination of electrons and holes and gets better the photocatalytic activity by trapping the photoinduced electrons.

Figure 2.6 Mechanism of TiO₂ photocatalysis: $h\nu_1$: pure TiO₂; $h\nu_2$: metal-doped TiO₂ and $h\nu_3$: nonmetal-doped TiO₂ (Adriana, 2008).

The mechanism of photoactivity of pure TiO₂ and TiO₂ doped with metal and nonmetal species are represented in Figure 2.6. In the case of pure TiO₂, the photocatalytic mechanism is initiated by the absorption of the photon $h\nu_1$ with energy equal to or greater than the band gap of TiO₂ producing an electron-hole pair on the surface of TiO₂ nanoparticle. An electron is promoted to the conduction band (CB) while a positive hole is formed in the valence band (VB). Excited-state electrons and holes can recombine and dissipate the input energy as heat, get trapped in metastable surface states, or react with electron donors and electron acceptors adsorbed on the semiconductor surface or within the surrounding electrical double layer of the charged particles. The photoactivity of metal-doped TiO₂ can be explained by a new energy level produced in the band gap of TiO₂ by the dispersion of metal nanoparticles in the TiO₂ matrix. An electron can be excited from the defect state to the TiO₂ conduction band by photon with energy equals $h\nu_2$. Additional benefit of transition metal doping is the improved trapping of electrons to inhibit electron-hole recombination during irradiation. Decrease of charge carriers recombination results in enhanced photoactivity (Hoffmann *et al.*, 1995).

Zhao and Yang, (2003) reviewed using of photocatalytic oxidation (PCO) to destruct volatile organic compounds in indoor air. They discussed that TiO₂ is widely used as a photocatalyst in various reactors due to its superior characteristics. For the PCO application, TiO₂ anatase is superior to rutile because the conduction band

location for anatase is more favorable for driving conjugate reactions involving electrons, and very stable surface peroxide group can be formed at the anatase but not on the rutile surface. And they also suggested that, intermediates produced during the PCO process can occupy the active site of the catalyst surface and result in deactivation of catalyst, so activity of the catalyst dropped.

Gaya and Abdullah (2008) reviewed an overview of the dramatic trend in the use of the TiO₂ photocatalyst for remediation and decontamination of wastewater. They mentioned that titania has played a much larger role than another semiconductor photocatalysts. Extensive literature analysis has shown many possibilities in improving the efficiency of photodecomposition over titania by combining the photoprocess with either physical or chemical operations. The resulting combined processes revealed a flexible line of action for wastewater treatment technologies. The choice of treatment method usually depends upon the composition of the wastewater.

Sun *et al.* (2008) studied the degradation of orange G (OG) on nitrogen-doped TiO₂ photocatalysis under visible light and sunlight irradiation. The result showed that not only the N-doped TiO₂ caused the new absorption band but also the photosensitized oxidation mechanism originated from the azo dyes themselves and contributed to the higher visible light activity. Therefore, the N-doped TiO₂ catalyst had higher the degradation OG than undoped TiO₂ catalyst under visible light. In contrast, the undoped TiO₂ catalyst exhibited high photocatalytic activity under sunlight irradiation.

Amini and Ashrafi (2016) studied photocatalytic degradation of rhodamine B (RB), methylene blue (MB), and acridine orange (AO) under solar light irradiation using TiO₂ and ZnO nanoparticles. The results showed that the degradation of RB in the absence of photocatalyst was very slow. When the TiO₂ catalyst was added, the degradation was complete faster. But the activity decreased when using the ZnO as catalyst. They suggested that the TiO₂ is chemically inert and stable with respect to photocorrosion and chemical corrosion, while the ZnO is unstable. The degradation of MB for two catalysts was complete in the same time but in absence light, the removal is not obvious. For pH effect, they found that the TiO₂ followed order pH 5 > 7 > 9 and 9 > 7 > 5 for the ZnO. And the degradation of AO by using

these catalysts, degradation percentage of AO increased almost linearly with time. They concluded that the TiO₂ and ZnO were found to be an effective catalyst for the destruction of industrial dyes.

2.3 Photocatalytic Degradation Mechanism of Zinc Oxide

Although TiO₂ currently represents to be a benchmark photocatalyst for the degradation of organic dyes and pollutants mainly due to its excellent performance; however, the photocatalytic activity of TiO₂ is limited because of the easily recombination of photogenerated electrons and holes. Moreover, TiO₂ shows lower absorbance value. Composite of semiconductor to promote the separation efficiency of photogenerated charge and extend the range of excite spectrum have been investigated.

One of the most popular metal oxides is zinc oxide (ZnO), which is a wide band-gap n-type semiconductor with unique properties such as good transparency, high electron mobility, and high electrochemical stability. It has been widely used in chemical sensor, surface acoustic wave device, and photoanode films of solar cell. Very highly reducing electrons and oxidizing holes are photogenerated on ZnO under UV light irradiation. Besides holes, h⁺, the main oxidizing species in water are hydroxyl radicals, OH[•]. Other oxidizing species such as singlet oxygen, hydroperoxyl radicals and superoxide ions play a minor role in photocatalytic transformations in liquid-liquid reactions (Coronado *et al.*, 2008). In addition, Zn²⁺ is a very important oxidation state. The presence of Zn²⁺ can act as the following mechanism (Rauf *et al.*, 2011).

Although ZnO presents higher electron mobility than TiO₂, which should favor electron transport, its chemical stability is poor, giving rise to filter effect, that is, a layer of inactive organic-Zn²⁺ insoluble complexes.

ZnO is sometimes preferred over TiO₂ for degradation of organic pollutants due to its high quantum efficiency, especially for the production of peroxides. The photodegradation mechanism of organic pollutants in ZnO has been claimed to be similar to that of TiO₂. Furthermore, according to the band edge position, as the conduction band of TiO₂ is lower than that of ZnO, the former can act as a sink for the photogenerated electrons. The photogenerated electrons of the ZnO conduction band will be transferred to the conduction band of TiO₂, while the photogenerated electrons of TiO₂ will remain in the conduction band of TiO₂. Since the holes move in the opposite direction from the electrons, the photogenerated holes of the TiO₂ valence band will be transferred to the valence band of ZnO, which makes charge separation more efficient as shown in Figure 2.7 (Shifu *et al.*, 2008).

Figure 2.7 Schematic diagram of electron-hole separation process (Shifu *et al.*, 2008).

Perez-Gonzalez *et al.* (2015) studied photocatalytic activity and properties of TiO₂-ZnO thin film to degrade methylene blue. The results are explained in terms of the (TiO₂)_{1-x}-(ZnO)_x, with x value in range 0.00 to 1.00. From the experiment, they discussed that the degradation activity of film increased with the TiO₂ content. The BET surface and the crystallinity showed opposite behaviors as a function of x value.

Therefore, $x = 0.00$ showed the lowest BET surface area and the highest crystallinity, resulting in the best photocatalytic performance. However, ZnO has been reported to show greater degradation activity than TiO₂ for specific organic dyes. They concluded that the high crystallinity seemed to be the most relevant factor for the degradation activity because it indicated low surface defects, low amorphous content and reduces the recombination rate.

Sakthivel *et al.* (2003) studied solar photocatalytic degradation of acid brown 14 by using ZnO and TiO₂ as photocatalysts. The results showed that the rate of degradation of two catalysts increased with increasing initial dye concentration then drastically decreased due to maximum concentration value exceeded. The rate of degradation of these catalysts increased linearly with catalyst loading, but the higher amount of catalysts can result in decreasing the efficiency. For both ZnO and TiO₂, the adsorption of dye was high at low pH range. The degradation rate of TiO₂ was high at low pH, in contrast to ZnO. The acid brown 14 was converted completely into colourless and degraded by using ZnO was faster than TiO₂. They concluded that ZnO was the most active photocatalyst in the degradation of acid brown 14 using sunlight as an energy source because it absorbed large fraction of solar spectrum.

Liao *et al.* (2004) studied photocatalytic activity of ZnO doped TiO₂ by sol-gel method and SO₄²⁻/TiO₂/ZnO modified by sulfating the dry gels ZnO/TiO₂ with H₂SO₄ solution. In this study, they used zinc sulfate as precursor of zinc. The results showed that the addition of zinc could enhance the activity of catalyst, and if the catalyst was a mixture of anatase and rutile TiO₂, the activity was also improved. They found that the stronger the acidity, the catalytic activity was higher. The photocatalytic activity decreased with the increase in the calcination temperature. And they also compared the activities of several catalysts before and after sulfating, the result showed that the activity of SO₄²⁻/TiO₂/ZnO was higher than that of TiO₂ doped by single ZnO or TiO₂ treated with single H₂SO₄. They concluded that the sulfating ZnO/TiO₂ with sulfuric acid resulted to dramatic enhancement.

Zhang *et al.* (2007) studied preparation of photocatalytic nano-ZnO/TiO₂ film with vacuum vaporized and sol-gel methods. The oxidation efficiency of the ZnO/TiO₂ was higher than the pure TiO₂ film and ZnO film. Therefore, the ZnO/TiO₂ film can largely enhance the photocatalytic degradation efficiency of organic compounds.

Moreover, ZnO increased concentration of free electrons in TiO₂. Effect of pH showed that the photocatalytic oxidation of organic compounds increased with the pH value.

Konyar *et al.* (2012) studied effect of sintering on photocatalytic efficiencies of self-supporting ZnO/TiO₂ composite plates, which was fabricated at a molar ratio of ZnO:TiO₂ = 1:1. Then, the plates were sintered in air at range 600-700°C to retain ZnO and TiO₂. The results showed that the surface area was decreased with increasing the sintering temperature. Moreover, when the sintering temperature increases, the amount of pure ZnO and TiO₂ decreased while the amount of photocatalytically inactive phases, such as Zn₂TiO₄ or Zn₂Ti₃O₈, increased. The decrease in the surface area values resulted in low degradation efficiency. They concluded that heat treatment at temperature as low as 600°C reduced the interdiffusion between ZnO and TiO₂.

2.4 Isopropanol

Isopropanol, isopropyl alcohol, or 2-propanol is a compound with chemical formula C₃H₈O and has a molecular structure as shown in Figure 2.8.

It is a sharp, colorless, and flammable liquid with a characteristic alcoholic odor and completely miscible (mixes completely) with most solvents, including water. It is also commonly used in cosmetics, skin and hair products, perfumes, pharmaceuticals, lacquers, dyes, cleaners, antifreezes, and other chemicals (www.dow.com/webapps/msds/msdssearch.aspx). Moreover, it is a common organic reagent present at high concentrations in the wastewater and volatile in nature. This organic compound poses direct or indirect harm to irritate and burn the skin and eyes, prolonged contact can cause a skin rash, itching, dryness, and redness and may be toxic to kidneys, liver, skin, central nervous system. Repeated high exposure can cause headache, dizziness, loss of coordination, unconsciousness, and even death. And it is a dangerous fire hazard (nj.gov/health/eoh/rtkweb/documents/fs/1076.pdf).

Figure 2.8 Molecular structure of isopropanol ([www.chemicalbook.com /Chemical ProductProperty_EN_CB8854102.htm](http://www.chemicalbook.com/ChemicalProductProperty_EN_CB8854102.htm)).

In addition, isopropanol is the major organic ingredient in wastewater of semiconductor manufacturing industry. The efficiency of traditional wastewater treatment processes using physical-chemical or microorganism decomposition approaches is limited. Wastewater containing organic solvents that are not decomposed deteriorates the quality of water in the environment, while its volatile nature results in air pollution that affects the health of factory workers and residents in the neighborhood (Chen and Mao, 2007). Isopropanol and its metabolite, acetone, act as central nervous system depressants (Burkhart and Kulig, 1990). Besides, isopropyl alcohol wastewater contains many other refractory and complex organic compounds, e.g., fluoride and suspended solids, which not only introduce direct or indirect contamination to environment but also are harmful to human health (Lin and Kiang, 2003).

Furthermore, it was found that acetone was solely detected as an intermediate product from the photocatalytic degradation of isopropanol. The isopropanol is degraded to form acetone, and acetone is further oxidized into carbon dioxide and water as shown in Eqs. (2.22) and (2.23), respectively (Chavadej *et al.*, 2008).

Bickley *et al.* (1973) used rutile TiO_2 and studied the photocatalyzed oxidation (PCO) in isopropanol vapor. The isopropanol quickly reacted to form acetone and H_2O . Acetone was then displaced by H_2O and appeared in the gas stream.

Adsorbed acetone was photocatalytically oxidized at a distinctly slower than isopropanol oxidized to acetone. Instead, acetone oxidized to strongly adsorbed intermediate, and the continuation of PCO was observed by O₂ uptake. The authors concluded that CO₂ decreased in O₂ uptake rate on samples pretreated at higher temperatures was due to lower concentrations of surface OH groups, which played a role in the PCO process by increasing O₂ photoadsorption. Moreover, no reaction occurred in the absence of UV light and only a small amount of acetone was formed in the absence of O₂ in the gas stream.

Chavadej *et al.* (2008) studied the photocatalytic degradation of 2-propanol by using platinum, titania, and platinum loaded on titania as photocatalysts. The result showed that the activity of either platinum or titania alone was greatly low in the photocatalytic degradation but increased for platinum loaded on titania. Increasing of the catalyst dosage and initial concentration of 2-propanol resulted in increasing the rate of degradation. The degradation rate increased with decreasing pH solution because of better adsorption of 2-propanol on the surface of catalyst. However, it increased again in the pH of solution was around 12 because the hydroxyl radical formation rate increased. Moreover, a high dissolved oxygen level gave a much higher degradation rate, since it can act as electron scavenger. And in this work, acetone was detected as an intermediate product.

Chen *et al.* (2009) studied photocatalytic properties of nanostructured PbSnO₃ photocatalysts with particulate and tubular morphologies for isopropyl alcohol (IPA) degradation under visible light irradiation. The gaseous IPA was gradually oxidized through an acetone intermediate to CO₂. The results revealed that the photocatalytic activities for IPA degradation over these catalysts were in the order of nanoparticle > nanotube > bulk material, which was consistent with that of BET surface areas. And they found that the degradation of IPA over these catalysts was only driven by light irradiation. They concluded that the larger surface area means much more active sites and better crystallinity which resulted in the increase of photocatalytic activity since it could reduce electron-hole recombination rate.

Salazar and Nanny (2010) investigated the aqueous photocatalytic degradation of small polar organic compounds (SPOCs) that bear hydrogen-bonding capabilities but do not readily adsorb on the TiO₂ catalyst like isopropanol and acetone.

This study suggested that small aliphatic alcohols and ketones may adsorb to the TiO₂ catalyst in contact with their aqueous solution through the formation of hydrogen bonds with the surface hydroxyl groups. The result showed that the fastest degradation rates of acetone and isopropanol occurred at conditions where the rate of hydroxyl radical production was more favorable such as in alkaline pH.

Wang and Egerton (2013) compared the effect of chromium on photo-oxidation of propan-2-ol, for which hydroxyl radicals were the catalytically active intermediates and stearic acid oxidation, which proceeds via direct hole transfer. For the photo-oxidation of propan-2-ol, the amount of acetone product increased linearly with time, and the effect of increasing amount of chromium dopant was less than 0.01% that was little affected but decreased significantly for more than 0.1% of chromium. By contrast, photocatalytic oxidation of stearic acid decreased with increasing concentration of chromium. They suggested that the initial increase in the propan-2-ol oxidation activity was associated with the oxidation state of Cr greater than 3 but that at higher chromium concentrations the activity for both stearic acid and propan-2-ol are decreased because of increased recombination induced by Cr³⁺ ions that substitute for Ti⁴⁺ in the rutile lattice.

Lu *et al.* (2016a) studied photodegradation of gaseous isopropyl alcohol (IPA) at ppb level in internal-illuminated monolith photoreactor (IMR) by using TiO₂ and Ag/TiO₂ as photocatalysts. The experimental results showed that, increasing the contents of Ag on TiO₂, the removal efficiency was increased because of the higher surface barrier. As a result, the electron-hole pair separation enhanced due to their space charge layer became narrower than TiO₂. However, if the presence of Ag was too much, it can be resulted in a decrease in the photocatalytic ability. Possible reasons were the electrostatic interaction between negatively charged Ag sites, and the excessive coverage of Ag can mask the incident light on TiO₂ surface.

2.5 Oxidative Energy Storage Model of TiO₂

TiO₂ has been widely used in our every daylife as a pollution abatement catalyst for various applications based on its oxidative and reductive energy converted from light energy. However, the uses of TiO₂ as a photocatalyst still have some limitation to activate the formation of photo-excited electrons and holes. Some researchers attempted to modify TiO₂ by doping it with both metallic and non-metallic substances in order to reduce band gap energy of the metal oxide, so its photocatalytic activity under the visible light can be obtained (Luo *et al.*, 2011). Additionally, the use of TiO₂ as a catalyst for pollution abatement in the absence of both UV and visible light, which can be applied for indoor air quality, is still challenging. In this regard, the concept of using TiO₂ in combination with other lower band gap metal oxides, capable of functioning as a kind of energy storage substance, has been developed (Tatsuma *et al.*, 2001).

Working mechanism of the mixed metal oxides can be described as following. In the presence of light, TiO₂ will be photo-excited and electrons/holes are generated. Some of electron can be transferred to the lower band gap metal oxide and stored in intermediate compound form. Then, in the dark, electron from the intermediate compound will be released and transferred back to the system. In other words, stored electron in the lower band gap metal oxide compound will serve as a source of electron for catalytic activity of the system in the dark. Moreover, the electron can also interact with oxygen in ambient, leading to the mixed metal oxides also work under versatile illumination condition including UV irradiation, visible light illumination and, in the dark (Ngaotrakarnwiwat, 2013).

Recently, the energy storage of photocatalyst has been attracting and investigated by doping an active semiconductor or p-n junction semiconductor. When an n-type semiconductor (TiO₂) is joined with a p-type semiconductor, a p-n junction is formed. The region, where the p-type and n-type semiconductors, are joined is called p-n junction, as shown in Figure 2.9. At equilibrium, the inner electric field makes the p-type semiconductor region have the negative charge, while the TiO₂ region have the positive charge (Dai *et al.*, 2013).

Figure 2.9 p-n junction of semiconductor (www.physics-and-radio-electronics.com).

Each free electron that is crossing the junction from the n-side to fill the hole in the p-side atom creates a negative ion at p-side. Similarly, each free electron that left the parent atom at the n-side to fill the hole in the p-side atom creates a positive ion at the n-side. Negative ion has more number of electrons than protons. Hence, it is negatively charged. Thus, a net negative charge is built at the p-side of p-n junction. Likewise, positive ion has more number of protons than electrons. Hence, it is positively charged. So, a net positive charge is built at n-side of the p-n junction.

Figure 2.10 Negative and positive barrier of semiconductor (www.physics-and-radio-electronics.com).

The net negative charge at the p-side of the p-n junction prevents further flow of free electrons crossing from the n-side to the p-side because the negative charge

present at the p-side of the p-n junction repels the free electrons. Comparably, the net positive charge at the n-side of the p-n junction prevents further flow of holes from the p-side to n-side.

Thus, immobile positive charge at the n-side and immobile negative charge at the p-side near the junction acts like a barrier or wall and prevents further flow of free electrons and holes, as shown in Figure 2.10. The region near the junction where flow of charges carriers are decreased over a given time and finally results in empty charge carriers or full of immobile charge carriers is called depletion region. The depletion region is also called as depletion zone, depletion layer, space charge region, or space charge layer. The depletion region acts like a wall between p-type and n-type semiconductor and prevents further flow of free electrons and holes, as shown in Figure 2.11 (www.physics-and-radio-electronics.com).

Figure 2.11 Depletion region of semiconductor (www.physics-and-radio-electronics.com).

Two kinds of models for storing the oxidative energy of TiO_2 were proposed, p-n junction model and mediation model.

2.5.1 p-n Junction Model

In the former, a redox-active p-type semiconductor is combined with TiO₂ to form a p-n junction, as shown in Figure 2.12.

Figure 2.12 p-n junction model for the oxidative energy storage photocatalysts (Takahashi and Tatsuma, 2005).

Semiconductors consist of a p-type and an n-type, where the n-type has a high electron concentration, and the p-type has a high hole concentration. The connection of the two types resulting in the move of excess electrons in the n-type material to the p-type side and the excess holes from the p-type material to the n-type side. An n-type semiconductor like TiO₂ adsorbs photon having energy equal to or higher than its band gap energy. With each photon of the required energy (i.e. wavelength), electrons rise to the unoccupied conduction band, leading to excited state conduction band electron and leaving the positive valence band holes (h^+) at the valence band. Later, the electrons then transfer from the p-type (electron donor) to the valence band of the n-type (electron acceptor) semiconductor at the junction between the p- and n-type semiconductors. The holes at the p-type are not stable and need intercalation (x^-) from an electrolyte for stabilization, as shown in Figure 2.12. The energy storage of TiO₂ with the p-type semiconductor takes place with the below model. The p-n heterojunction photocatalyst accelerates the separation of electron-hole pairs. Therefore, the p-n heterojunction photocatalyst has attracted much attention in recent years (Takahashi and Tatsuma, 2005).

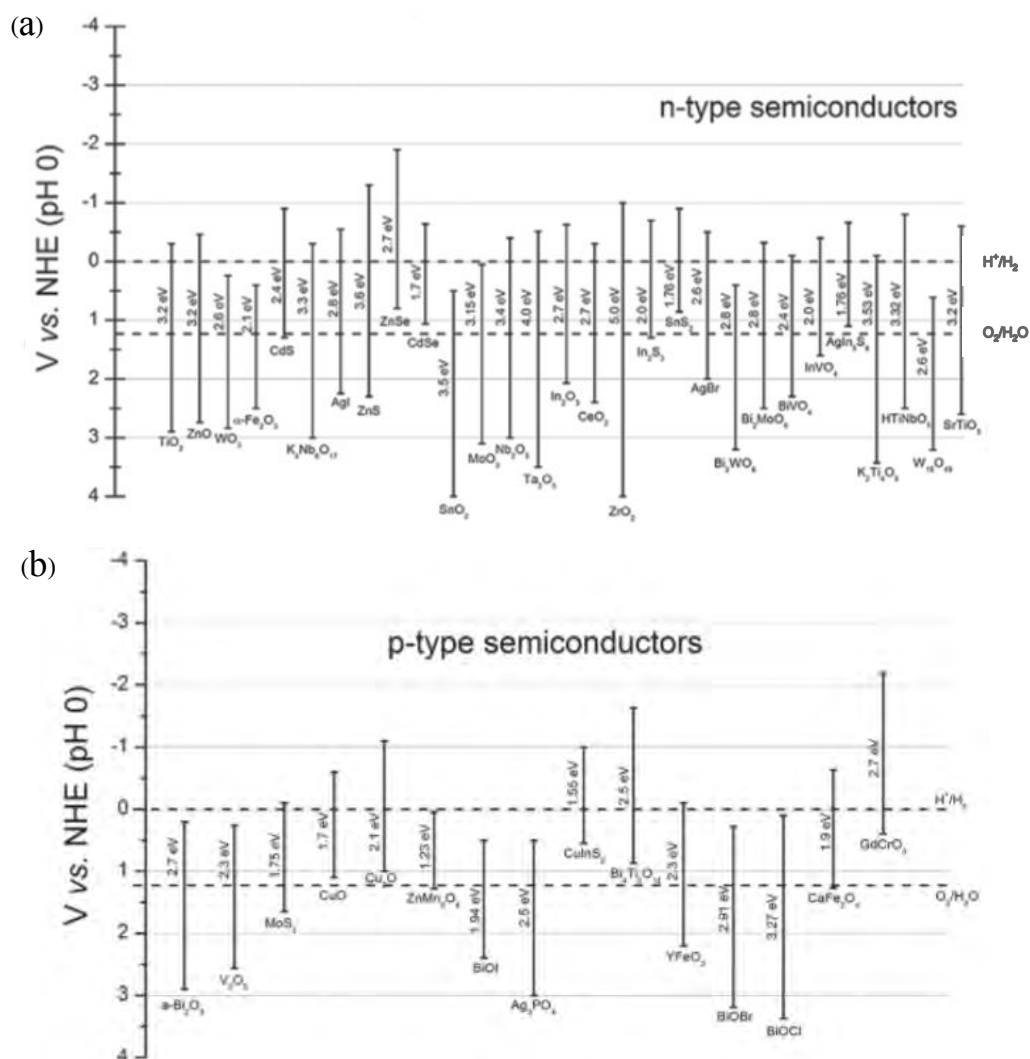

Figure 2.13 Band gaps and band positions of a) n-type semiconductors and b) p-type semiconductors used for composite photocatalyst heterojunction and values taken from references given in the article (Roland, 2014).

2.5.2 Mediation Model

In the mediation model, an oxidant like O_2 , which is photocatalytically produced by the oxidation of water adsorbed on TiO_2 , diffuses and oxidizes a redox-active material.

The first step of the mediation model resembles the p-n junction model. That is a TiO_2 photocatalyst absorbs photon having energy equal to or higher than its band gap energy. With each photon of the required energy (i.e. wavelength), electrons

rise to the conduction band, leading to excited state conduction band electrons and leaving the positive valence band holes (h^+) at the valence band. On the other hand, unlike the p-n junction model, the electrons from the mediation (H_2O_2) then transfer to the valence band of TiO_2 for electrical neutrality, and the electrons of redox active material are transferred to mediation. As the result of the redox active material is widened in stability, intercalation (x^-) from an electrolyte for stabilization, as shown in Figure 2.14. The energy storage of TiO_2 with a redox active metal takes place with the below mechanism (Takahashi and Tatsuma, 2005).

Figure 2.14 Mediation model for the oxidative energy storage photocatalysts (Takahashi and Tatsuma, 2005).

Takahashi and Tatsuma (2005) studied oxidative energy storage ability of a TiO_2 - $Ni(OH)_2$ bilayer photocatalyst. The TiO_2 and $Ni(OH)_2$ are reported to be an n-type and p-type semiconductor, respectively, hence, a p-n junction forms at the interface. They found that under UV light, electrons in the TiO_2 valence band are excited to the conduction band, and holes generate in the valence band. The oxidative energy storage, $Ni(OH)_2$ is oxidized to $NiO_x(OH)_{2-x}$ by the holes, and it could be turned from colorless to brown. After that, the brown-colored film could be turned back to colorless by electrochemical reduction. They suggested that the efficiency would be improved by increasing the junction area. And the stored oxidative energy can be discharged electrochemically or used for the chemical oxidation of various species.

Shifu *et al.* (2008) studied photocatalytic activity of p-n junction photocatalyst p-ZnO/n-TiO₂, which was evaluated by photocatalytic reduction of Cr₂O₇²⁻ and photocatalytic oxidation of methyl orange (MO). The experiment results showed that the photoreduction activity of p-ZnO/TiO₂ increased with the increase in the amount of doped p-ZnO up to 2.0 wt%. When the amount of doped was higher than the optimal amount, the activity decreased as the amount of doped p-ZnO increased. On the other hand, the photocatalytic oxidation activity of p-ZnO/TiO₂ decreases rapidly with the increased in the amount of doped p-ZnO. They concluded that the p-n junction photocatalyst p-ZnO/TiO₂ had higher photocatalytic reduction activity, but lower photocatalytic oxidation activity. As the p-ZnO species can trap the hole, the photocatalytic reduction activity was enhanced greatly.

Yang *et al.* (2010) investigated oxidation and mineralization of methanol and formaldehyde by the stored oxidative energy and used TiO₂-Ni(OH)₂ as a photocatalyst. The results showed that the bilayer film turned brown after electrochemical oxidation to NiO_x(OH)_{2-x} and bleaching of the film due to reduction of NiO_x(OH)_{2-x}. Then, the methanol can be oxidized to CO₂ by the stored oxidative energy. When the initial methanol concentration was increased, the mass conversion efficiency decreased because stored charges were consumed during the methanol oxidation. For the oxidation of formaldehyde, since it was easier to oxidize than methanol, hence, it was also oxidized to CO₂ by photoelectrochemically stored oxidative energy like methanol.

Lian *et al.* (2011) studied oxidative energy behavior of a porous nanostructured TiO₂-Ni(OH)₂ bilayer photocatalyst under UV light. They reported that the oxidative energy storage performance could be enhanced, resulting from its porous structure and nanostructured Ni(OH)₂ particles that may provide high specific surface area, fast redox reactions, and shortened diffusion path in solid phase. And the electrolytes with relatively high OH⁻ concentration facilitated the oxidative energy storage because it led to high crystal nucleation rate of Ni(OH)₂, thus the nanostructured particles were obtained. But, if the nucleation rate was too high, the particle sizes increased.

Dai *et al.* (2013) studied photoelectrocatalytic (PEC) activity of p-n junction Co₃O₄/TiO₂ nanotube arrays (NTs) that was evaluated by degradation of

methyl orange (MO). The results showed that the decrease in the MO concentration in the presence of unmodified TiO₂ NTs was small. On the contrary, 92% of MO was degraded by Co₃O₄/TiO₂ thus it exhibited significantly enhanced PEC activity. The degradation rate of Co₃O₄/TiO₂ was also faster than that over TiO₂ NTs. They discussed that Co₃O₄ is a p- type semiconductor, while TiO₂ is an n- type semiconductor. Therefore, the p-n junction is formed, which can improve separated efficiency of photogenerated carriers and inhibit their recombination.

2.6 Sol-gel Method for Thin Film Preparation

A number of methods, films such as sol-gel, sputtering, chemical vapor deposition, have been employed for the fabrication of TiO₂ thin. Each of these methods has its own advantages and disadvantages (Oshani *et al.*, 2014).

For large area films preparation, the sol-gel method is apparently superior to vapor deposition methods. This scheme not only provides simplicity, low cost, and feasibility, but also proving as a precise approach to control doping concentrations (Lu *et al.*, 2016b). This method is particularly attractive because of the following reasons: good homogeneity, ease of composition control, low processing temperature, large area coatings, low equipment cost and good optical properties and it allows the tuning of the refractive index and thickness of the film by varying synthesis parameters (Znaidi *et al.*, 2012). Particularly, the sol-gel processes are efficient in producing thin film with high purity, transparent, multi-component oxide layers of many compositions on various substrates, including silica/glass plate, stainless steel plates, and aluminaplates (Oshani *et al.*, 2014).

Sol-gel is a process, in which dispersions of a colloidal suspension, known as the sol, is formed in a liquid by the hydrolysis of inorganic or metal organic precursors, which is then followed by gel formation (Gaya, 2014). Normally, precursors such as titanium alkoxide, titanium tetrachloride, and titanium halogenide are heated under very high calcination temperature to obtain the desired crystal properties and a good adherence on the support. During heating, OH groups from the catalyst surface and the support can react and evaporate a molecule of water, creating an oxygen bridge, thus increasing the adherence of the catalyst to the support.

To immobilize uniform catalyst film on a substrate by sol-gel method, dip-coating or spin-coating technique is employed. Automated coaters are commercially available, to keep operator error minimal and accurately maintain dipping speed of substrate and duration. In general, a dip coating apparatus equipped with an adjustable motor is used to immerse the support into a solution (gel form) and then withdrawn it at a certain speed. Therefore, this route is suitable for the production of a thin film photocatalyst. However, some drawbacks of the sol-gel method include the wide variation in the particle size distribution and the necessity of a calcination step for crystallization, which may result in the melting of the substrate. To improve the drawbacks of substrate, there are many researches that studied sol-gel with dip-coating over fiberglass, woven fiberglass, aluminum plate, and glass slide as a substrate of thin film catalyst (Shan *et al.*, 2010).

Figure 2.15 Schematic simplify diagram of sol-gel method associate with dip-coating (Angelo *et al.*, 2013).

In regarding to spin-coating, it is a very convenient technique widely applied to uniform thin film deposition. As it is shown in Figure 2.16, an amount of solution is dropped on the substrate, which is fixed on the spin-coater, and then it is rotated at high speed in order to spread the fluid by centrifugal force. It can be considered as a special case of solution crystal growth, which allows the formation of highly oriented layered perovskites on a substrate, while the solvent is evaporating off. On the other hand, spin-coating enables deposition of hybrid perovskites on various substrates, including glass, plastic, quartz, silicon and sapphire. Selection of the substrate, the

solvent, the concentration of the hybrid in the solvent, the substrate temperature, and the spin speed are relevant parameters for this technique. In addition, post deposition low-temperature annealing ($T < 250^{\circ}\text{C}$) of the hybrid films are sometimes employed to improve crystallinity and phase purity. David (2001) compared the traditional deposition technique for inorganic semiconductors with the spin-coating method and reported that the latter, spin-coating method does not require cumbersome equipment and gives high-quality films in quite short time (several minutes) in room environment.

Figure 2.16 Schematic of the spin coating process (Sohrab *et al.*, 2016).

Actually, in order to realize a layer with the desired thickness, the concentration of perovskites solution can be adjusted and keep the other spin-coating parameters (spin speed, acceleration, and spin duration) fixed. Generally, homogeneous 2D layered perovskite films with a thickness from 10 nm to 100 nm can be obtained by carefully selecting the parameters: less concentrated solutions give thinner layers. Therefore, the choice of the solvent is important because the solubility for both organic and inorganic must be considered (Sohrab *et al.*, 2016).

Bahadur *et al.* (2006) studied morphologies of spin process derived thin films of ZnO using zinc nitrate and zinc acetate as precursor materials. The experiment showed that the films of ZnO prepared by using zinc acetate were smoother and more uniform than the zinc nitrate. Both of films were found to be crystalline in nature. The crystallite size of the nanograins in the zinc nitrate derived films was found to be smaller than the films grown by zinc acetate. They concluded that zinc acetate was the precursor material, which was suitable for preparation of ZnO films using sol-gel process or spray pyrolysis.

Lewkowicz *et al.* (2014) studied surface morphology and optical properties of TiO₂ thin films deposited on glass with the sol-gel spin coating technique. In the experiment, they used different annealing temperatures (380-900°C). The results showed that the TiO₂ thin films without annealing were amorphous but their structure shifted through the anatase to rutile phases. The amorphous nature of TiO₂ was obtained using the sol-gel methods, and the step of heat-treatment was required. The increasing of the annealing temperature, the porosity of the TiO₂ thin films decreased because of shrinkage and densification of the films. The TiO₂ films crystallize was the anatase phase between 380-700°C, while the rutile phase existed above 800°C.

Leonard *et al.* (2016) studied photocatalytic performance of SiO₂ and Ag-SiO₂ doped TiO₂ films by dip-coating process and powders to degrade methylene blue under UV light. The result showed that in the case of powders, crystallization was hindered by SiO₂ and Ag particles incorporation into the TiO₂ matrix, resulting to a decrease of the photocatalytic activity. In the case of thin film, crystallization was not influenced by the presence of SiO₂ and Ag particles. And the result also showed that films were slowly degraded due to surface contamination with carbon but both of SiO₂ and Ag can improve this problem. They concluded that the thin film can fully play their role of electron traps leading to an enhanced photocatalytic activity.

CHAPTER III EXPERIMENTAL

3.1 Chemicals and Equipment

3.1.1 Chemicals

1. Bis(2,4-pentanedionato)-titanium (IV) oxide (reagent grade, $\text{TiO}(\text{C}_5\text{H}_7\text{O}_2)_2$, TCI Co., Ltd, Japan)
2. Zinc oxide (99%, ZnO, analytical grade, Ajax, Australia)
3. Isopropanol (99.7%, analytical grade, Carlo Erba Reagents, Italy)
4. Polyethylene glycol (100%, MW = 1000, $(\text{H}(\text{OCH}_2\text{CH}_2)_n\text{OH}$, Wako, Japan)
5. Sodium hydroxide (analytical grade, NaOH, Merck, Germany)
6. Hydrochloric acid (37%, HCl, analytical grade, Labscan, Thailand)
7. Ethanol (99.8%, $\text{C}_2\text{H}_5\text{OH}$, analytical grade, Merck, Germany)
8. Nitric acid (65%, HNO_3 , Merck, Germany)
9. Cleaning solution (MICRO-90, Cole-Parmer, USA)
10. Deionized water

3.1.2 Equipments

1. Photocatalytic reactor
2. Spin coater (WS-650Mz-23NPPB)
3. pH meter
4. Vacuum pump (GAST0523-101Q-SG588DX)

3.2 Experimental Procedures

3.2.1 ZnO doped on TiO₂ Bilayer Films

A glass slide plate as the substrate was ultrasonically cleaned with the cleaning solution (MICRO-90) before coating. The TiO₂ film was coated on the glass plate with the solution containing 3 g of bis(2,4-pentanedionato)-titanium(IV) oxide and 3 ml ethanol by spin coating technique at 1,500 rpm for 20 s and calcined at 400°C for 1 h. For the second layer, the ZnO layer was prepared by spin coating technique at the same conditions as above. TiO₂-sol was synthesized by sol-gel technique using titanium isopropoxide (TIPP) as a precursor. Firstly, 1.4 ml of 70% HNO₃ was diluted with 200 ml deionized water then added to 16.7 ml of TIPP under vigorous stir for a couple of days until clear solution was obtained. The resulting solution was dialyzed by a membrane to obtain TiO₂ sol at a pH condition of 3.5 ± 0.1 . The solution containing TiO₂-sol with ZnO and polyethylene glycol was prepared. ZnO particles were obtained from the calcination temperatures at 400, 500 and 600°C for 1 h, and denoted as 400ZnO, 500ZnO and 600ZnO, respectively. Then, the ZnO layer was coated on the TiO₂ layer and was calcined at 350°C (heating rate 10°C min⁻¹) for 1 h to obtain a ZnO/TiO₂ bilayer film.

3.2.2 Photocatalytic Activity

A 200 ml of a 100 ppm isopropanol solution was for the photocatalytic activity experiments. Adsorption of isopropanol on the bilayer films was allowed before the start of each experiment. An experiment started by turning on the uv-light source. The solution was subject to 2 h illumination before the light source is turned off for 2 h. The uv-light was then turned on for another 2 h before off for 2 h. The experiment setup was blocked from any interference from other light sources by using black box throughout the experiment. The solution samples were taken every hour for quantitative analysis by using gas chromatography (Agilent, 6890N).

3.2.3 Physical Characterization

The morphology of ZnO/TiO₂ bilayer films was examined by scanning electron microscope (SEM, Hitachi, S-4800). The crystalline structure and crystal size

was determined by X-ray diffraction measurement (XRD, Rigaku, Smartlab). The surface area, pore size, and pore volume are measured by Brunauer–Emmett–Teller surface area analysis (Quantachrome, Autosorb-1) and particle size diameter is analyzed by particle size analyzer (Malvern, Mastersizer X).

3.3 Analytical Technique

3.3.1 Gas Chromatography with Flame Ionization Detection (GC-FID)

The solution was tested every hour for quantitative analysis by using gas chromatography with flame ionization detection, (Agilent 6890N, DB-WAX column, 30 m × 0.32 mm, ID of 0.53 μm) which operated at 80°C and was connected to a flame ionization detector with H₂ as the carried gas, that use to determine the amount of product, the degradation of isopropanol was calculated by Eq 3.1.

$$\%Degradation = \frac{C_n - C_{n-2}}{C_n} \times 100\% \quad (3.1)$$

Where C_n was a concentration at time (2,4,6,8 hr)

3.3.2 XRD Spectrometer

TiO₂ film, ZnO powder, and ZnO/TiO₂ bilayer films were detected X-ray diffractometer (XRD, Rigaku, Smartlab), with Cu- k_α radiation ($\lambda = 1.5406 \text{ \AA}$), 40 Kv, 30 mA) in the 2θ range of 20-80° with 3°/min scanning rate and step interval was 0.02°, to analyze crystal structure, chemical composition, and physical properties of thin films.

The Crystallite size (L) of selected sample were estimated using Scherrer's equation (Eq. 3.2).

$$L = \frac{0.9\lambda}{B \cos\theta} \quad (3.2)$$

Where $k = \text{constant}$ ($k = 0.9$)

λ = wavelength of the X-ray

B = FWHM (Full Width at Half Maximum) width of the diffraction peak

θ = diffraction angle

3.3.3 SEM Spectrometer

Surface characterization of TiO₂ film, ZnO powder, and ZnO/TiO₂ bilayer films were carried out by scanning electron microscopy (SEM, Hitachi, S-4800).

3.3.4 Brunauer–Emmett–Teller Surface Area Analysis

ZnO particles at different calcination temperature were characterized by BET surface area analyzer with N₂ adsorption at liquid nitrogen temperature (Quantachrome, Autosorb-1) to measure surface area, pore size, and pore volume of ZnO particles.

3.3.5 Particle Size Analyzer

The particle sizes of the ZnO powder at different calcination temperature were measured by Malvern's mastersize-2000 particle size analyzer (Malvern, Mastersizer X).

CHAPTER IV

RESULT AND DISCUSSION

4.1 Catalyst Characterization

The activity of ZnO/TiO₂ bilayer films for the photocatalytic degradation of isopropanol with and without UV illumination was investigated. In order to explain the properties of bilayer films, the photocatalyst films were characterized by scanning electron microscopy, Brunauer-Emmett-Teller surface area analysis, particle size analyzer, and X-ray diffractometer.

4.1.1 Scanning Electron Microscopy

The surfaces ZnO/TiO₂ photocatalyst bilayer films were studied from the SEM micrographs by using scanning electron microscopy (SEM, Hitachi, S-4800). The results are shown in Figures 4.1-4.2. Figure 4.1 shows the SEM micrographs of first TiO₂ layer, which shows the uniform surface. TiO₂ solution seems to cover well over the glass plate substrate. Figure 4.2 shows the SEM micrographs of ZnO/TiO₂ bilayer films, ZnO calcined at 600°C, which are denoted as 600ZnO/TiO₂. From Figure 4.2a, it can be seen that the ZnO particles disperse on the TiO₂ layer. Figure 4.2b shows the porous structure of ZnO particles resulted from the removal of PEG in the preparation step. However, using PEG as a template, the well-ordered network pattern with a large specific surface area can be obtained as reported by Liu *et al.* (2005). It is the porosity of the second layer that allows isopropanol to adsorb on the first layer.

Figure 4.1 SEM micrographs of TiO₂ film at (a) 400X and (b) 10,000X magnification, respectively.

Figure 4.2 SEM micrographs of ZnO/TiO₂ film at (a) 400X and (b) 10,000X magnification, respectively.

4.1.2 Particle Size Analysis

The particle size of ZnO was studied by the particle size analyzer (Malvern, Mastersizer X). The effect of the calcination temperature on the particle size diameter of ZnO is shown in Figure 4.3. It can be seen that by increasing the temperature, the particle size increases, which can be ascribed by the agglomerated particles. The results are consistent with those from the SEM micrographs, as shown in Figure 4.4. The ZnO particles are in the shape of hexagonal, which can be classified as wurtzite ZnO.

Figure 4.3 ZnO particle size diameters with different calcination temperature.

Figure 4.4 SEM micrographs of (a) 400ZnO, (b) 500ZnO, and (c) 600ZnO at 70,000X magnification.

4.1.3 Brunauer–Emmett–Teller Surface Area Analysis

The specific area, pore volume, and pore size of ZnO powder at various calcination temperature were measured (Table 4.1). The decrease in the surface area, pore volume, and pore size of ZnO can be observed when the calcination temperature is increased. That may be due to the collapse of the porous framework. However, the specific area, pore volume and pore size of 500ZnO, 600ZnO and 700ZnO are not significantly different.

Table 4.1 Effect of calcination temperatures on the physical properties of ZnO

Temperature (°C)	S _{BET} (m ² g ⁻¹)	Pore volume (cm ³ g ⁻¹)	Pore size (Å)
400	10.59 ± 0.95	2.31x10 ⁻² ± 0.12	81.35 ± 0.61
500	5.66 ± 0.38	0.99x10 ⁻² ± 0.03	69.79 ± 1.11
600	5.14 ± 0.36	0.92x10 ⁻² ± 0.02	71.82 ± 0.35
700	4.32 ± 0.35	0.81x10 ⁻² ± 0.02	69.13 ± 0.41

4.1.4 X-ray Diffraction

The photocatalysts were studied by XRD technique. Figure 4.5 shows the XRD patterns of ZnO/TiO₂ bilayer films compared with TiO₂ and ZnO. TiO₂ in the thin films is of anatase form (with main peak at (101)). In addition, it is clear from the XRD pattern that ZnO is well crystallized and can be classified as hexagonal wurtzite modification, with dominating (101) peak. The XRD pattern of the ZnO/TiO₂ bilayer films is composed of TiO₂ and ZnO structures. The intensity of the main peaks of TiO₂ and ZnO in the bilayer films are more or less the same with those of TiO₂ and ZnO films. And it can be seen that, there is no indication for formation of any mixed compound.

Figure 4.5 XRD patterns of TiO₂, ZnO and ZnO/TiO₂ bilayer films.

When the calcination temperature of ZnO/TiO₂ increases, the crystallinity of catalyst increases as indicated by the increase of the diffraction peak sharpness, Figure 4.6. The diffraction peak sharpness and narrowness improve with respect to the calcination temperature, and the full-width at half-maximum (FWHM) values are decreased with the increase in the calcination temperature (Rohani *et al.*, 2010).

The XRD patterns of ZnO/TiO₂ with different ZnO loadings are shown in Figure 4.7 indicating that the peak patterns of all ZnO loadings are similar.

Figure 4.6 XRD patterns of 400, 500 and 600ZnO/TiO₂ bilayer films.

The average crystallite size of ZnO was calculated according to Scherrer's equation. The three highest peaks ((100), (002), and (101) planes) of ZnO were selected for this calculation. The results are given in Table 4.2. It is clear that there is an improvement in the crystallinity of ZnO by increasing the calcination temperature (Zulkiflee *et al.*, 2016).

Table 4.2 Crystallite size of ZnO/TiO₂ bilayer films estimated using the XRD technique and Scherrer's equation

Temperature (°C)	400	500	600
Crystallite size (nm)	25.29	25.95	26.22

Figure 4.7 XRD patterns of ZnO/TiO₂ bilayer films with different ZnO loading.

4.2 Photocatalytic Activity

ZnO/TiO₂ was used as a bilayer film catalyst for the photocatalytic degradation of isopropanol (IPA). The first layer was coated by TiO₂ and then covered by the mixture of ZnO/TiO₂ as the second layer. The effect of adsorption was eliminated by immersing the film in the isopropanol solution for 12 h. The reactor was blocked from any disturbance from other light sources by using a black box. The conditions for the photocatalytic reaction were 30°C, 150 rpm of stirred speed, 5 lamps of UV light, 200 ml of 100 ppm isopropanol solution, and reaction time for 8 h. The amounts of either TiO₂ on the first layer or TiO₂ alone are 0.004 ± 0.001 g, and the amount of ZnO alone on the glass plate is 0.003 ± 0.001 g.

4.2.1 Photocatalytic Activity of TiO₂, ZnO, 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ Films

Figure 4.8 Photocatalytic degradation of isopropanol in unadjusted pH as a function of operating time by the TiO₂, ZnO, 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ films with the UV illumination for 8 h.

100 ppm of isopropanol solution with the unadjusted pH of 6.3 are subject to UV light alone and with the presence of photocatalysts (Figure 4.8). The illumination in the absence of photocatalysts results in very little degradation of isopropanol at 8 h, whereas, in the presence of photocatalysts, higher degradation of isopropanol can be observed at 8 h up to 47.8-74.0%.

Figure 4.8 shows that the degradation of isopropanol increases with the increase in the operating time. At 8 h, TiO₂ shows the lowest activity, 47.8% degradation of isopropanol. In addition, the ZnO film shows higher degradation than TiO₂, up to 61.9%. The reason for the higher activity of ZnO is due to the absorption of more light quanta because the band gap of ZnO is 3.3 eV, and the quantum

efficiency is significantly larger than TiO₂ (3.2 eV). Other than that, the lower activity of TiO₂ results from recombination occurred at the interface due to fewer electron and hole scavengers present in the photocatalyst (Amalina *et al.*, 2017). And 600ZnO/TiO₂ shows the highest photodegradation activity, 74.0%. The activity of 500ZnO/TiO₂ and 400ZnO/TiO₂ activity is about the same, 52.3% and 51.5%, respectively. At the beginning, the activity of 400, 500, and 600ZnO/TiO₂ are the same, but the activity of 400ZnO/TiO₂ and 500ZnO/TiO₂ becomes lower than 600ZnO/TiO₂ after 4 h. This might be ascribed to the photocorrosion phenomenon in the ZnO particles that results in the reduction the availability of surface active sites for the reaction to take place (Kodihalli and Timmappa, 2012). The activity of 600ZnO/TiO₂ works more effectively corresponding to the maximum formation of hydroxyl radicals on the ZnO/TiO₂ surface resulted from low recombination of electron-hole pairs, resulting in the destruction of the target organic pollutant (Yu *et al.*, 2006). When the bilayer film is contacted with the UV-irradiation, the photogenerated electrons of the ZnO conduction band will be transferred to the conduction band of TiO₂, while the photogenerated electrons of TiO₂ will remain in the conduction band of TiO₂. Since the holes move in the opposite direction from the electrons, the photogenerated holes of the TiO₂ valence band will be transferred to the valence band of ZnO, which makes charge separation more efficient. Furthermore, according to the band edge position, as the conduction band of TiO₂ is lower than that of ZnO, the former can act as a source for the photogenerated electrons (Shifu *et al.*, 2008). On the other hand, ZnO can increase concentration of free electrons in the conduction band of TiO₂, which implies that the charge recombination is reduced in the process of electron transport (Zhang *et al.*, 2007).

Figure 4.9 Photocatalytic degradation of isopropanol per catalyst loading weight in unadjusted pH as a function of operating time by the TiO₂, ZnO, 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ films with the UV illumination for 8 h.

Figure 4.9 shows the photocatalytic degradation of isopropanol per weight of loading of TiO₂, ZnO, 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ films. It can be seen that the degradation per weight of loading of 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ bilayer films are lower than TiO₂ and ZnO alone, which is possible that the bilayer films have more thickness and weight of catalyst than TiO₂ and ZnO alone that resulted in cannot allow light to go through and activate radicals from the first TiO₂ layer; thus, the lower degradation efficiency.

Under light irradiation, isopropanol is gradually oxidized through an acetone intermediate, and the concentration of isopropanol and acetone changes as shown in Figure 4.10. It is clear that the concentration of acetone increases continually, while the concentration of isopropanol decreases with the long-term irradiation. Isopropanol photocatalytic degradation mechanisms are shown in Figure 4.11.

Figure 4.10 Changes of isopropanol concentration and acetone from isopropanol degradation as a function of operating time over the (a) TiO₂, (b) 400ZnO/TiO₂, (c) 500ZnO/TiO₂ and (d) 600ZnO/TiO₂ films with the UV illumination for 8 h.

Figure 4.11 Isopropanol photocatalytic degradation mechanism (Kimball and Dowden, 1978).

4.3 Energy Storage

4.3.1 Energy Storage of TiO_2 Films

To set a baseline for energy storage of photocatalyst films, the TiO_2 film was first used. TiO_2 used for the film preparation was calcined at 400°C . The conditions for the photocatalytic reaction were 30°C , 150 rpm of stirred speed, 5 lamps of UV light, 200 ml of 100 ppm isopropanol solution at unadjusted pH. The UV light was turned on for 2 h and turned off for 2 h until 8 h operating time. From Figure 4.12, the result indicates that the degradation of isopropanol is about 16.5% after the first illumination and 14.1% after the second illumination. The reduction in the degradation of isopropanol is possibly caused by the low activity of TiO_2 alone. Furthermore, TiO_2 activity is limited by two main factors: the inability to absorb light and the fast recombination of photogenerated electron and hole (Adriana, 2008). Furthermore, intermediate products might be there, which are not desorbed from the catalyst surface; therefore, isopropanol cannot adsorb on the surface that causes low degradation efficiency. Thus, TiO_2 shows low photocatalytic activity even the photocatalytic system is under illumination. Without illumination, the highest degradation rate is about 2.6%. It possible that the amount of isopropanol may adsorb on the catalyst

surface. Moreover, the n-type TiO₂ first layer cannot form the p-n catalyst; thus, the degradation is very low.

Figure 4.12 Photocatalytic degradation of isopropanol in unadjusted pH as a function of operating time by the TiO₂ film with and without UV illumination.

4.3.2 Energy Storage of ZnO Films

From Figure 4.13, the result shows that the degradation of isopropanol is about 17.0% after the first illumination and 16.5% after the second illumination. This indicates that ZnO has higher activity than TiO₂ under UV illumination. However, without illumination, the highest degradation rate is about 1.9%. Like the TiO₂ films, it possible that the amount of isopropanol may adsorb on the catalyst surface. Moreover, the p-type ZnO first layer cannot form the p-n catalyst; thus, the degradation is very low.

Figure 4.13 Photocatalytic degradation of isopropanol at unadjusted pH as a function of operating time by the ZnO film with and without UV illumination.

4.3.3 Effects of UV Exposure Time of the 600ZnO/TiO₂ Bilayer Film on the Oxidation Energy Storage

Exposure time of the 600ZnO/TiO₂ bilayer film to UV irradiation was also studied. The UV light was turned on 1 h and turned off 1 h until 8 h, turned on 2 h and turned off 2 h until 8 h, and turned on 3 h and turned off 3 h until 12 h.

The results show that the reaction by exposure time of 2 h has higher energy storage efficiency than the reaction by exposure time of 3 h. For the UV exposure for 1 h, the degradation without illumination is lower than zero. It may be possible that having too short of the exposure time does not have enough electrons and holes resulting in a lower extent of isopropanol degradation, and the adsorbed isopropanol could desorb from the catalyst. Thus, the UV exposure time for 1 h is not suitable for energy storage.

Figure 4.14 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, UV irradiation for 1 h and turn off 1 h until 8 h.

Figure 4.15 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, UV irradiation for 2 h and turn off 2 h until 8 h.

Figure 4.16 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, UV irradiation for 3 h and turn off 3 h until 12 h.

4.3.4 pH Effects on the ZnO/TiO₂ Bilayer Film Activity on the Photocatalytic Reaction

In this study, the effect of pH of isopropanol solution on the photodegradation was examined at pH 3.0, which was adjusted by HCl, and the unadjusted pH (pH 6.3).

Figure 4.17 pH effect of 600ZnO/TiO₂ film on the photocatalytic degradation of isopropanol at various pH with the UV illumination for 8 h.

It was observed that the degradation efficiency with ZnO/TiO₂ decreases with the decrease in the pH exhibiting maximum of degradation at unadjusted pH, 74.0% (Figure 4.17). pH simply influences the surface charge of the photocatalyst, affecting the adsorption of the substrate onto the surface charge of the photocatalysts known as reaction site as well as the hydroxyl radical (OH[•]) formation (Chavadej *et al.*, 2009). The pH effect on the photodegradation of isopropanol in the presence of ZnO/TiO₂ can be explained by using zero point charge (pH_{pzc}). The pH_{pzc} of ZnO is approximately 8.5 and that for TiO₂ is about 5.3; therefore, about 7.0 could be the resultant pH_{pzc} of bilayer films. Thus, the surface of the photocatalyst becomes positively charged at lower pH, but at higher pH, it becomes negatively charged (Habib *et al.*, 2013). Although isopropanol can adsorb preferentially on the positively charged surface in the acidic condition, the degradation at pH 3.0 is less than at the unadjusted pH as the photocorrosion of ZnO may take place at lower pH. Bahnemann *et al.* (1987)

mentioned that ZnO is unstable due to incongruous dissolution to yield $\text{Zn}(\text{OH})_2$ on the ZnO particle surfaces and thus leading to catalyst inactivation.

4.3.5 pH Effects on the ZnO/TiO₂ Bilayer Film Activity on the Oxidation Energy Storage

ZnO/TiO₂ bilayer films were used as a photocatalyst to study the effect of oxidation energy storage on the photocatalytic activity with and without UV illumination. Isopropanol solution was adjusted to pH 3.0 by HCl. Figure 4.18 indicates the concentration of isopropanol at various times compared with isopropanol initial concentration by different pH, which shows the degradation rate of the isopropanol solution at unadjusted pH is higher than at pH 3.0 for both with and without light illumination.

Figure 4.18 Concentration of isopropanol at various time compared with isopropanol initial concentration by the ZnO/TiO₂ bilayer films with different pH.

From Table 4.3, with UV illumination, the degradation rate of isopropanol solution at unadjusted pH by using ZnO/TiO₂ bilayer films shows the highest rate. As described before, unadjusted pH can improve the reaction site more than at pH 3.0. Other than that, at pH 3.0, might be occurred the presence of inhibition on the surface of catalyst could occur. However, the result without UV illumination shows that the degradation rate of isopropanol at unadjusted pH by ZnO/TiO₂ is also higher than at pH 3.0. Therefore, we will focus on the degradation of isopropanol at unadjusted pH by ZnO/TiO₂ to find the other optimum factors.

Table 4.3 Reaction rates of isopropanol by the ZnO/TiO₂ bilayer films with different pH

	Reaction rate (x10 ⁵ s ⁻¹)			
	Operating time (h)*			
	2	4	6	8
Unadjusted pH	2.90	1.53	1.97	1.11
pH 3.0	2.50	0.79	1.85	0.51

* The UV illumination was on for two hours (2 h operating time). Then, the illumination was off for two hours (4 h operating time). After that, turning it on for two more hours (6 h operating time) and off for the last two hours (8 h operating time).

4.3.6 Effects of ZnO Loading of the 600ZnO/TiO₂ Bilayer Film on the Oxidation Energy Storage

Figures 4.19-4.22 show the degradation of isopropanol from ZnO/TiO₂ at various ZnO loadings. The results show that the isopropanol solution can be degraded with every ZnO loading with and without UV illumination. That be due to the p-n junction of ZnO/TiO₂, with ZnO and TiO₂ as a p-type semiconductor (p-ZnO) and n-type semiconductor (n-TiO₂), respectively. When doping p-ZnO into n-TiO₂, a number of micro p-n junction are formed. At equilibrium, the p-ZnO region is negatively charged, while the n-TiO₂ is positively charged. Under UV irradiation, electron-hole pairs are generated, then the holes flow into the negative field p-ZnO,

and the electrons flow into the positive field n-TiO₂. Thus, the electron-hole pairs are separated effectively by the p-n junction. Moreover, the p-ZnO can act as a source for photogenerated electrons that are transferred to the conduction band of n-TiO₂, while the photogenerated electrons of n-TiO₂ remain in the conduction band of n-TiO₂. In addition, the holes move in the opposite direction from the electrons, the valence band of p-ZnO (Shifu *et al.*, 2008). It was reported that the holes could be trapped by p-ZnO into the Zn²⁺ form (Jing and Lu, 2003). Takahashi and Tatsuma (2005) reported that the photogenerated holes are transported into the p-semiconductor for the oxidative energy storage. From this reason, the p-n junction of ZnO/TiO₂ contributes to energy storage.

In order to examine the effect of ZnO loading on the 600ZnO/TiO₂ bilayer films, ZnO/TiO₂ was prepared at 4, 8, 15, and 19 mol% ZnO loadings (per total film). Figures 4.19-4.22 show the photocatalytic degradation of isopropanol with various ZnO loadings at unadjusted pH. When the ZnO loading is increased from 4 mol% to 15 mol%, the degradation activity with and without UV illumination increases until the loading hits 15 mol% and then decreases when the loading is increased to 19 mol%. Moreover, the ZnO has higher activity than TiO₂ because it has wide energy band gap; thus, it can harvest wide UV region. Chavadet *et al.* (2008) mentioned that increasing the catalyst loading resulted in increasing the generation of active species to react with organic molecules, consequently increasing the reaction rate, as shown in Table 4.4. And, with higher loading, the dispersion of ZnO particle on TiO₂ surface may decrease, resulting in larger ZnO particle. Bansal *et al.* (2009) mentioned that, with the high dose of catalyst, there was a decrease in the UV light penetration; hence, the photoactivated electron-hole pairs decrease. Therefore, the light masking effect by ZnO particles on the TiO₂ surface also has a negative factor on the photocatalytic activity.

Figure 4.19 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, 4 mol% ZnO, with and without UV illumination.

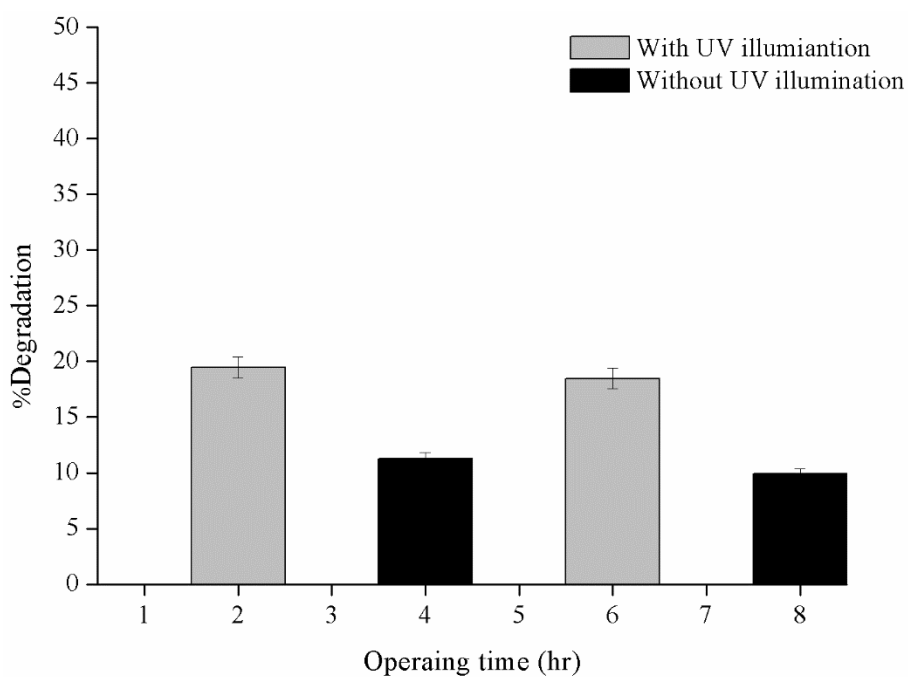

Figure 4.20 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, 8 mol% ZnO, with and without UV illumination.

Figure 4.21 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, 15 mol% ZnO, with and without UV illumination.

Figure 4.22 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, 19 mol% ZnO, with and without UV illumination.

Figure 4.23 Concentration of isopropanol at various time compared with isopropanol initial concentration by the ZnO/TiO₂ bilayer films with different ZnO loading with and without UV illumination.

Figure 4.23 shows the concentration of isopropanol at various time compared with isopropanol initial concentration and the reaction rate of isopropanol by ZnO/TiO₂ bilayer films with different ZnO loadings, also shown in Table 4.4.

Table 4.4 Reaction rates of isopropanol by the ZnO/TiO₂ bilayer films with different ZnO loading

	Reaction rate (x10 ⁵ s ⁻¹)			
	Operating time (h)*			
	2	4	6	8
4 mol% ZnO	2.47	0.87	1.91	0.61
8 mol% ZnO	2.70	1.26	1.83	0.80
15 mol% ZnO	2.90	1.53	1.97	1.11
19 mol% ZnO	2.57	1.09	1.81	0.67

*The UV illumination was on for two hours (2 h operating time). Then, the illumination was off for two hours (4 h operating time). After that, turning it on for two more hours (6 h operating time) and off for the last two hours (8 h operating time).

The rate of photocatalytic degradation can be expressed by Eq (4.1).

$$r = \frac{d\left(\frac{C}{C_0}\right)}{dt} \quad (4.1)$$

where r is the rate of reaction (s⁻¹), C is the isopropanol concentration at various times (ppm), C_0 is the isopropanol initial concentration (ppm), and t is the operating time (s). Table 4.4 shows the rate of photocatalytic degradation of isopropanol by using the ZnO/TiO₂ bilayer films with different ZnO loading. It can be clearly seen that the reaction rate with using 15 mol% ZnO is the highest followed by 8, 19, and 4 mol%, respectively.

4.3.7 Effects of ZnO Calcination Temperature of the ZnO/TiO₂ Bilayer Film on the Oxidation Energy Storage

To investigate the optimum oxidation energy storage, ZnO particles were calcined at 400, 500, and 600°C, denoted as 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂, respectively. And the bilayer films were prepared at 15 mol% ZnO loading. Figures 4.24-4.26 show the photocatalytic degradation of isopropanol with the tested catalysts. These experimental results indicate that higher photocatalytic degradation activity is observed in the early stage of reaction, and become lower until at 8 h. This can be ascribed to the photocorrosion phenomenon on the surface of catalyst during the photocatalytic reaction contributed to low degradation efficiency (Feng *et al.*, 2014). Moreover, the lower efficiency of photocatalytic degradation can be explained by the low photo-generated electrons and holes precipitated in the reaction (Wang *et al.*, 2005).

The results also show that 600ZnO/TiO₂ has the highest photodegradation efficiency. This may be corresponding to the maximum formation of hydroxyl radicals on the ZnO/TiO₂ surface resulted from low recombination of electron-hole pairs, resulting in the destruction of the target pollutant. The hydroxyl radicals are known to be powerful and non-selective oxidizing agent, which are responsible for partial or complete mineralization of several organic chemicals (Pardeshi and Patil, 2009). The 600ZnO/TiO₂ photocatalyst shows the highest crystallite size and high particle size, but low BET surface area. Generally, the BET surface area is considered as a key parameter but, in this research, although the 400ZnO/TiO₂ has the highest surface area, it has the lowest photocatalytic degradation of isopropanol. Di and Haneda (2003) reported that the photocatalytic activity rises with the increase in the crystallinity, but decrease with the BET surface area indicating that crystallinity, rather than BET surface area, played a more important role on the photocatalytic activity. Kodihalli and Timmappa (2012) indicated that the increase in the calcination temperature resulted in the increase in the particle size and in crystallinity, which was helpful to enhance the photocatalytic activity. Muhammad *et al.* (2015) also reported that the nanomaterials, which had higher crystallinity, may provide direct path for the transfer of electron and decrease the charge recombination, thus increasing the efficiency. Furthermore, the higher crystallinity had more

conductive zone in contact with the degrading organic compound to produce a better photocatalytic activity.

Moreover, the photocatalytic degradation from the bilayer films is also higher than TiO₂ and ZnO films. Without illumination, the optimum condition is 600°C, and the highest photocatalytic degradation of isopropanol can be as high as 14.8%. The photocatalytic activity of ZnO/TiO₂ prepared in any other preparation condition is lower than that of 600°C heat treatment.

Figure 4.24 Photocatalytic degradation of isopropanol at unadjusted pH by the 400ZnO/TiO₂ film, 15 mol% ZnO, with and without UV illumination.

Figure 4.25 Photocatalytic degradation of isopropanol at unadjusted pH by the 500ZnO/TiO₂ film, 15 mol% ZnO, with and without UV illumination.

Figure 4.26 Photocatalytic degradation of isopropanol at unadjusted pH by the 600ZnO/TiO₂ film, 15 mol% ZnO, with and without UV illumination.

Figure 4.27 Photocatalytic degradation of isopropanol at unadjusted pH by the 700ZnO/TiO₂ film, 15 mol% ZnO, with and without UV illumination.

Figure 4.27 shows the photocatalytic degradation of isopropanol with 700ZnO/TiO₂, it can be seen that when the calcination temperature increases up to 700°C, the degradation becomes lower, which is possibly due to the decrease in specific surface area, pore size and pore volume, and the increase of particle size; hence, the reduction of active sites for the reaction.

Figure 4.28 Concentration of isopropanol at various time compared with isopropanol initial concentration by the ZnO/TiO₂ bilayer films with different ZnO calcination temperature with and without UV illumination.

Furthermore, Figure 4.28 shows the concentration of isopropanol at various times compared with its initial concentration and the reaction rate of isopropanol by ZnO/TiO₂ bilayer films with different ZnO calcination, also shown in Table 4.5.

Table 4.5 Reaction rates of isopropanol by the ZnO/TiO₂ bilayer films with different ZnO calcination temperatures

	Reaction rate (x10 ⁵ s ⁻¹)			
	Operating time (h)*			
	2	4	6	8
400ZnO/TiO₂	2.13	0.92	1.82	0.80
500ZnO/TiO₂	2.29	1.19	1.82	0.96
600ZnO/TiO₂	2.90	1.53	1.97	1.11
700ZnO/TiO₂	2.40	1.02	1.77	0.61

*The UV illumination was on for two hours (2 h operating time). Then, the illumination was off for two hours (4 h operating time). After that, turning it on for two more hours (6 h operating time) and off for the last two hours (8 h operating time).

4.3.8. Photocatalytic degradation of TiO₂, 400ZnO/TiO₂, 500ZnO/TiO₂, 600ZnO/TiO₂, and ZnO Films on the Oxidation Energy Storage

Figure 4.29 shows the photocatalytic degradation on the oxidative energy storage ability of TiO₂, 400ZnO/TiO₂, 500ZnO/TiO₂, 600ZnO/TiO₂, and ZnO films. It can be seen that when the lights are off, the degradation per weight of catalyst loading of 400ZnO/TiO₂, 500ZnO/TiO₂, and 600ZnO/TiO₂ are higher than TiO₂ and ZnO alone. Therefore, the bilayers films contribute to energy storage ability. And, the degradation per weight of loading of 600ZnO/TiO₂ is higher than 500ZnO/TiO₂ and 400ZnO/TiO₂, respectively.

Figure 4.29 Photocatalytic degradation of isopropanol per catalyst loading weight on the oxidation energy storage in unadjusted pH as a function of operating time by the TiO₂, 400ZnO/TiO₂, 500ZnO/TiO₂, 600ZnO/TiO₂, and ZnO films with the UV irradiation for 2 h and turn off 2 h until 8 h.

CHAPTER V

CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

ZnO/TiO₂ bilayer photocatalyst films were prepared by spin coating method to test the photocatalytic degradation of isopropanol and their energy storage. From the photocatalytic activity study, ZnO/TiO₂ showed the highest isopropanol degradation about 74.0%. However, that was not the case when the weight of the film was taken into consideration. Furthermore, the degradation of ZnO/TiO₂ in the unadjusted pH solution was higher than at pH 3.0. From the investigation on the energy storage, 2-hour exposure time showed the best time to store energy to degrade isopropanol without illumination. 15 mol% of 600ZnO/TiO₂ was found to be optimum and exhibited the best activity in isopropanol degradation at unadjusted pH when there was no illumination. The highest degradation of isopropanol without illumination was about 14.8%. Moreover, when the weight of the films was included, the bilayer films still had the highest activity when there was no illumination.

5.2 Recommendations

From this study, the following recommendations are suggested:

1. Find other p-type semiconductors that could improve the efficiency of photocatalyst to degrade organic compounds during the reaction without illumination.
2. Use ZnO/TiO₂ bilayer films to degrade other organic compounds.
3. Use mixed of TiO₂ and ZnO in one layer to degrade organic compound

APPEDICES

Appendix A Standard X-ray Diffraction Powder Patterns of TiO₂

Appendix B Standard X-ray Diffraction Powder Patterns of ZnO

Appendix C Calculation sample of ZnO loadings on TiO₂ layer

The calculation of ZnO on TiO₂ layer can be calculated by

$$\% \text{ mol ratio} = \frac{\text{mol ZnO}}{\text{mol ZnO} + \text{mol TiO}_2}$$

For example;

Weight of the second layer = 0.00125 g

TiO₂ sol (on the second layer) = 0.0015 g

∴ ZnO on the second layer = 0.0015 – 0.00125 = 0.00025 g

TiO₂ (on the first layer) = 0.004 g

∴ The amount of TiO₂ total film = 0.0015 + 0.004 = 0.0055 g

From the mol ratio equation;

Mw of TiO₂ = 79.866

Mw of ZnO = 81.408

$$\text{Mol ratio} = \frac{\frac{0.00025}{81.408}}{\frac{0.00025}{81.408} + \frac{0.0055}{79.866}} = 0.0427 = 4 \text{ mol\% of ZnO per total film}$$

And the other mol% of ZnO per total film can be calculated by the same with this equation.

CURRICULUM VITAE

Name: Ms. Ratchawan Jarumanee

Date of Birth: November 25, 1992

Nationality: Thai

University Education:

2011-2014 Bachelor Degree of Industrial Chemistry, Faculty of Science,
Chiang Mai University, Chiang Mai, Thailand

Work Experience:

2013-2013 Position: Internship Student
(Quality Assurance)
Company name: Thai Parkerizing Company Limited,
Rayong, Thailand

Proceedings:

1. Jarumanee, R., Rangsunvigit, P., and Ngaotrakanwivat, P. (2017, May 23) Study on energy storage ability of ZnO/TiO₂ for photocatalytic degradation of isopropanol. Proceedings of The 8th Research Symposium on Petrochemical and Material Technology and The 23rd PPC Symposium on Petroleum, Petrochemicals, and Polymers, Bangkok, Thailand.

Presentation:

1. Jarumanee, R., Rangsunvigit, P., and Ngaotrakanwivat, P. (2017, June 12-15) Synthesis of bilayer films for photocatalytic degradation of isopropanol in the absence of light. Poster Presented at 2nd International Conference on Applied Surface Science (ICASS), Dalian, China.
