KEYWORD: hydrocarbon proxy/ *n*-alkane distribution/ lake sediment/ sea level/ water level/ paleoenvironment

Assuma Sainakum : USING *N*-ALKANE AS A PROXY TO RECONSTRUCT PALEOENVIRONMENT IN THALE NOI, PHATTHALUNG PROVINCE.

Advisor: Asst. Prof. AKKANEWUT CHABANGBORN, Ph.D. Co-advisor: Asst. Prof. Piyada Jittangprasert, Ph.D.

Normal alkane (*n*-alkane) is the widely used hydrocarbon proxy for the paleoenvironmental study because of their specific characteristic and resistance to microbial degradation. The *n*-alkanes from the sediment cores TLN-CP5 and TLN-CP7 from Thale Noi, Phatthalung Province, were analyzed and subsequently compared with those derived from the recent plant samples. The plant samples were taken from mangrove forests, i.e. true mangrove, back mangrove, and mangrove associate, based on the previous study on pollen analysis. The *n*-alkane distributions, the average chain length (ACL), the carbon preference index (CPI) and the proportion of aquatic components (P_{aq}) were further analyzed in order to reconstruct past environmental changes. For the modern plant samples, the *n*-alkane distributions, ACL and CPI values in each plant group are diverse and high uncertainty. These ambiguity results are possibly caused by growing environment influent on *n*-alkane synthesis and too small sample size to represent the entire plant groups. In contrast, the *n*-alkanes distribution and their parameters in lake sediment have obviously corresponded to change of paleoenvironment. Our results suggest that the change of C_{21} , C_{27} , C_{29} , and C_{31} abundances of *n*-alkane indicate the dynamic of vegetations and water level in the lake. C_{21} relate to the high-water level that opposing to C_{27} , C_{29} , and C_{31} . The ACL, CPI, and P_{aq} can be used to indicate a sea-level fluctuation. During about 8,300 to 8,000 cal yr BP, the ACL and CPI gradually increase that suggest a sea level regression. And then the ACL and CPI gradually decrease about 7,600 to 7,200 cal yr BP that correspond to a transgression. A high P_{aq} and increasing of ACL and CPI presence in the surface sediment demonstrate that freshwater has more influence than seawater after 7,200 cal yr BP to recent.

ACKNOWLEDGEMENTS

I would like to express my deepest thanks to my thesis advisors, Assistant. Professor Akkaneewut Chabangborn, Ph.D., who always gives me excellent advice, assistance, and encouragement in both thesis and my daily life. I appreciate everything which he gives me, especially his good will. And this thesis can't be turned out like this without his assistance and his exquisite.

I would like to thanks to my thesis co-advisor Assistant. Professor Piyada Jittangprasert, Ph.D. from Department of Chemistry, Srinakharinwirot University for her guideline in chemical technique and extract equipment.

I'm also extremely grateful to Assistant. Professor Penjai Sompongchaiyakul, Ph.D. that gives me the opportunity to join the tenth international workshop on the Fluvial Sediment Supply to the South China Sea at Jakarta. That gave me an excellent experience.

I'm thankful scientists and officers at Scientific and Technological Research Equipment Centre (STREC) and of Chulalongkorn University, who give instrument and software training for complete the result. And thanks to the lab staff of geochemical laboratory for facilitating all the time that the lab has done.

Specials thanks to Mr. Supawich Feungfu, Miss Worakamon Nudnara and Miss Arunee Karaket for many assistances and the laughter. I appreciate their friendship and encouragement.

Finally, I would also like to thank Mr. Narin Sukwatthanakorn and my family for the support. they provided me love and encouragement. This thesis would not have been succeeded without these people.

Assuma Sainakum

CHAPTER I

INTRODUCTION

1.1 Rationale

Climate is an average of weather, which is a modulation of many atmospheric variables, e.g. temperature, humidity, atmospheric pressure, and wind speed and direction, over a given period of time (Easterling et al., 1993). The gradual increase in temperature plays a key role in environmental changes, e.g. long frost-free season, violent droughts, heat wave, and strengthen and frequent hurricanes (Hoegh-Guldberg et al., 2007). The sea level change is also a potential indicator of global temperature variability because it has a closed relationship with the disruption of the ocean thermal and the continental ice sheets (Hoegh-Guldberg et al., 2007). In addition, recent studies point to the accelerating on sea level rise between 19th and 21st century under global warming (Hoegh-Guldberg et al., 2007). This transgression allows the saline intrusion into groundwater and surface water, which is caused by a decrease in the agricultural products (Easterling et al., 1993). Moreover, the accelerated rise in sea level triggers coastal erosion and coastal wetland loss (Wenner and Simmons, 2009). These physical impacts can be led to socio-economic problems, e.g. unemployment, food resources, and a decline in the gross domestic product. Despite the physical impact on the sea level rise are well known, the information on long-term sea level changes are necessary for the proper adaptation and application in the future.

The reconstruction of the past environment based on the geological archives, e.g. ice cores, speleothems, marine or lake sediments and evolution of geomorphology, can provide a longer time record than the instrumental observation (Fairall et al., 2003). This indirect information can be used to validate climate simulation for a better understanding of the environmental response on climate changes. The lake sediments are widely used for environmental reconstruction because of their simple chronology and deposition with various proxies (Meyers, 1997, 2003; Meyers and Ishiwatari, 1993). The lake sediments are generally not disturbed by external factors after deposition. Therefore, the sediment sequences have followed the law of superposition that the lower strata are older than their overlaid

layer (Jackson, 2006). Moreover, many proxies deposit with the sediments in the lake that can be classified into three groups: physical, biological and chemical proxies. The physical proxies are sediment characteristics including their composition, texture, structure, color, density or magnetic property (Last and Smol, 2006). The biological proxies are non-living organisms from plants and animals, such as pollen, spore, plant macrofossil, charcoal, ostracod, and diatom (Last and Smol, 2006). And the chemical proxies are fossil substances derived from living organisms that preserved in sediments, e.g. elemental composition, biogenic silica, and organic matter (Last and Smol, 2006).

Organic matter is complex organic compound, which generally consist of carbon, hydrogen and other elements that derived from the decomposition of living organisms by microbial activities (Meyers, 2003). The organic compounds are, for example, fatty acids, aliphatic hydrocarbons, isoprenoid compounds, alcohols and ketones, pentacyclic triterpenoid acids, steranes and triterpenes, sterols, carbohydrates, amino acids, and amino sugars, pigments, purines and pyrimidines (Hao et al., 2015; Peters et al., 2004). Among those organic matters, the biomarkers are organic compounds, which are commonly found in a specific organism, and contain stable structure under the sediment processes (Peters et al., 2004). Most of the biomarkers are lipid hydrocarbon that is generally divided into the saturated and unsaturated hydrocarbons. Normal alkanes (*n*-alkanes) are the saturated hydrocarbons consisting of carbon and hydrogen atoms that the carbon atoms arranged in a straight chain. The *n*-alkane have widely used as a proxy because of their resistance to microbial degradation (Meyers and Ishiwatari, 1993). Since the *n*-alkanes can be survived in the sediments for tens of millions of years and different organisms create a specific range of *n*-alkanes, they can be used to classify the provenance of organic matter in the sediments. These hydrocarbon proxies were here using to reconstruct the past environment in Thale Noi, Phatthalung Province.

Since plants surrounding the lake are a major source of organic matters in the sediments, the *n*-alkanes in the sediments are possibly derived from those vegetation (Pu et al., 2017). Furthermore, the vegetation dynamics in regarding to pollen analysis have been assumed to be recorded in the *n*-alkanes.

1.2 The objectives of this study consist of

1. To construct a database of *n*-alkanes distribution of mangrove plants in the tropical zone.
2. To reconstruct the paleoenvironment in Thale Noi, Phatthalung Province.

1.3 Expected outcome

1. Information of *n*-alkane distribution and their parameters of mangrove plants in the tropical zone.
2. Information on paleoenvironmental change around Thale Noi, Phatthalung Province.

1.4 Scope of works

Eight sediment cores were taken from Thale Noi during the field experiment in January 2015 (Yoojam, 2015). These sediment successions suggest that Thale Noi possibly consists of two sub-basins. Core TLN-CP5, which represent the east sub-basin, were studied in detail by using pollen analysis by Nudnara (2016), and physical and chronological analysis by Phountong (2016). However, the detailed study in the west sub-basin has not available. The site description and previous studies were reported in detail in Chapter 2.

The *n*-alkanes were using here as a proxy in order to understand the environmental history in Thale Noi. This study consists of two parts, i.e. modern leaf wax and sediments analysis. The methodology is presented in detail in Chapter 3. In order to cover all plant species classified by pollen in core TLN-CP5 by Nudnara (2016), the modern plant samples were taken from Thale Noi, Pattalung Province, Kung Krabaen Bay Royal Development Study Center (KKB), Chantaburi Province, and Khun Samut Chin Temple (KSC) and Pom Phra Chulachomklao (PPC), Samut Prakan Province. For the sediment analysis, cores TLN-CP5 and TLN-CP7 were selected in order to represent the western and eastern sedimentary sequences. Macroplant remains from TLN-CP7 were dated by radiocarbon dating technique using the accelerate mass spectrometer (AMS). The results of plant and sediment

analysis were present in Chapter 4. The reconstruction of environmental changes in the study area was discussed in Chapter 5 and concluded in Chapter 6.

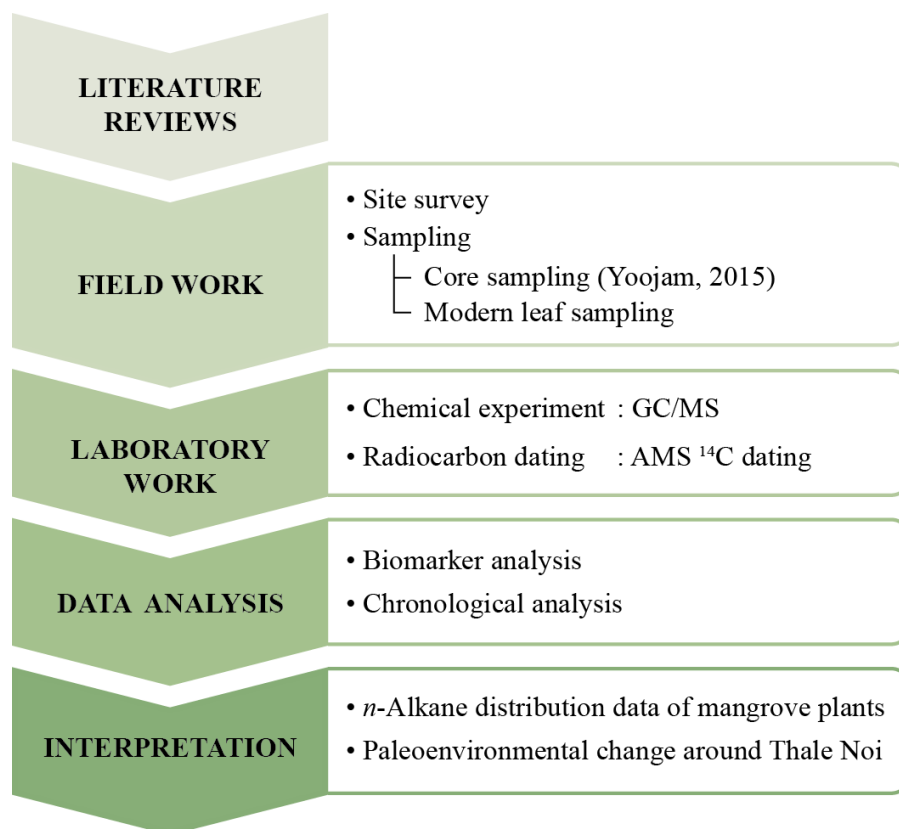

Figure 1 Thesis workflow.

CHAPTER II

LITERATURE REVIEWS

2.1 Study area

Thale Noi (7°50'N, 100°08'E) is a shallow freshwater lake that connects to the northern part of The Great Songkhla Lake, which is a lagoon on the east coast of Thai–Malay Peninsula (Fig. 2). The lake level in Thale Noi is possibly affected by not only runoff but also the sea-level changes in the Gulf of Thailand. Since this area is located in a tropical climate, and a tectonically stable region, it is a crucially important area for investigating the long-term fluctuation in the sea-level (Tjia and Liew, 1996).

Thale Noi is approximately 20 km far from the coast and covering the area of about 25 km² (Chaimanee et al., 1986). It is surrounded by flat plain with approximately 2 to 3 m above mean sea level (MSL) (Chaimanee et al., 1986; Somboon, 1990). The western part of the area is the Cretaceous granite mountain range and an undulated plain (Chaimanee et al., 1986; Pramojaneet al., 1986). The limestone mountain and clastic sedimentary rock can be found in the north and south, and scatter around the lake (Chaimanee et al., 1986) (Figure 3). Meanwhile, the eastern part of the lake is a flat plain and a strand plain next to the coastline. Consequently, the sediments are potentially eroded and transported from the western highland to the eastern lowland. The modern lake level is mainly supplied by precipitation, and many small canals in the north, east and west direction. The southern part of the lake is connected to the great Songkhla lake through 3 canals, i.e. Khlong Nang Riam, Khlong Ban Klang and Klong Yuan (Figure 2).

The climate in Thailand is mainly controlled by the northeast (winter) and southwest (summer) monsoons (Chawchai et al., 2013). The southwest monsoon transports humidity from the Indian Ocean and increases rainfall in Thailand from May to October. However, the precipitation in the study area is relatively low during the strengthening of the southwest monsoon. The precipitation gradual increases from October to February caused the transportation of humidity from the Gulf of Thailand to the study area by the northeast monsoon. The mean annual precipitation in this area is approximately 1,500-2,000 mm/yr (Horton et al., 2005).

Figure 2 Topography around Thale Noi and the location of coring points.

2.2 Sea-level fluctuation

Since Thale Noi is located on tropical climate and a tectonically stable region, the tectonic movement and glacial isostatic adjustment on sea-level change are possibly negligible (Tjia and Liew, 1996). These all together make this an interesting area for the long-term investigation in sea-level changes.

According to the Quaternary sediment analysis, the Great Songkhla Lake and its surrounding area including Thale Noi was a part of the Sundaland during the late Pleistocene (Chaimanee et al., 1986; Somboon, 1990). And it became flooding caused by a gradual sea level rise at about 8500 cal yr BP (Chaimanee et al., 1986; Pradit et al., 2009; Pramojanee et al., 1986). This transgression can be assessed by pollen and sediment analysis from nearshore Thale Noi by Horton et al. (2005) (Figure 5). However, the recent study of sediment sequences suggests two different lithostratigraphic between the western and eastern Thale Noi (Yoojam, 2016) (Figure 4). Moreover, the study of radiocarbon dating associated with pollen and sediment analysis by Nudnara (2017) and Phountong (2017) propose that Thale Noi had submerged under marine environment before 8300 cal yr BP (Figure 6). Regarding to Nudnara (2017) and Phountong (2017), the sea-level decreased from 8,300 - 8,050 cal

yr BP. The transgression from 8,050 - 7,600 cal yr BP can be reconstructed, while Horton et al. (2005) mention a gradual regression from 7,780 - 2,535 cal yr BP. These discrepancies can be explained by the low dating resolution of the record from nearshore Thale Noi, which makes it difficult to capture the abrupt environmental change (Horton et al., 2005). Moreover, Nudnara (2017) and Phountong (2017) suggest the subsequent stillstand of sea-level from 7,600 - 7,200 cal yr BP. Unfortunately, the radiocarbon dating results from Nudnara (2017) and Phountong (2017) are limited at 7,200 cal yr BP. However, Chaimanee et al. (1986) found that the sea-level was lowering near the study area at approximately 6,490 – 6,758 cal yr BP. Pollen and sediment records from nearshore Thale Noi further suggest the transformation from a mangrove swamp to a freshwater lake during 2,720-2,350 cal year BP (Horton et al., 2005).

Figure 3 Quaternary geologic map of Cha-uat district, Phatthalung Province (Chaimanee., 1986).

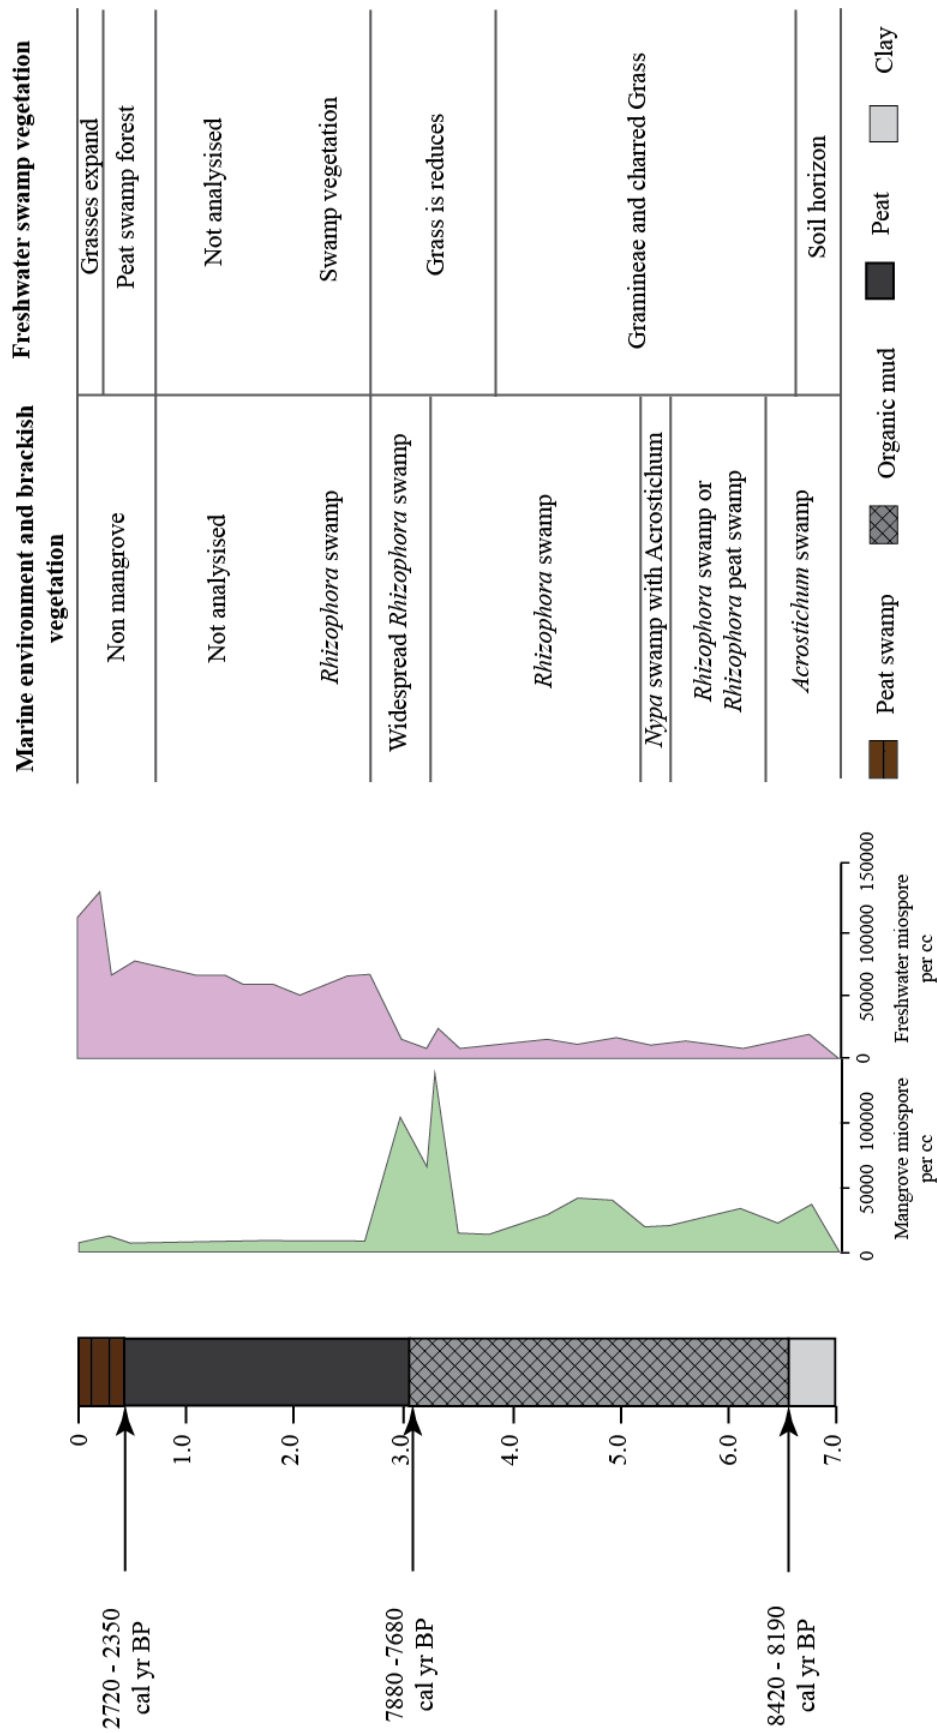

Figure 5 Thale Noi Core 3 (TN-3) paleoenvironmental interpretation based on sedimentological and palynological data (Horton et al., 2005). The coring point (TN-3) was shown in figure 2.

Figure 6 Graph compares lithostratigraphic column with age depth model, LOI₅₀, PSD and pollen assemblage distributions reported by Phountong (2016) and Nudnara (2016).

2.3 Biomarker

Biomarkers are complex organic compounds consist of carbons, hydrogens, and other elements such as oxygens, and nitrogen, etc., which are derived from diverse living organisms and stored in soil and sediment organic matter (Eglinton and Hamilton, 1967; Eglinton and Eglinton, 2008). The living organisms are classified into three major domains, including archaea, eubacteria, and eukarya (Peters et al., 2004). Archaea and eubacteria are prokaryotic cells that lack a nuclear membrane, unlike eukarya, that contains a nuclear membrane and complex organelles(Peters et al., 2004). The difference of morphology, biochemistry and metabolic pathway in the three domains organisms control the kinds of biomarkers that originated by the organisms.

The metabolism in an organism can be described as an autotrophic, heterotrophic, chemotrophic and phototrophic term (Peters et al., 2004) that rely on carbon and energy sources. Autotrophs use carbon dioxide (CO₂) as a carbon source for their thriving and obtain energy from sunlight or the oxidation of inorganic compounds to use in the process of converting CO₂ into organic compounds and create a store of chemical energy (Peters et al., 2004). In contrast, heterotrophs use organic compounds from the decomposition process from other organisms as carbon and energy sources for their growth (Peters et al., 2004). Chemotrophs take carbon and energy from the oxidation of inorganic compounds, such as H₂, H₂S, and NH₃ (Peters et al., 2004). Phototrophs are organisms which use sunlight for their metabolic process. They have the substrates for either anoxygenic photosynthesis/non-O₂ producing, which is a process that generates sulfur instead of oxygen, or oxygenic photosynthesis/ O₂-producing.

Table 1 Classification of organisms based on their metabolisms (Peters et al., 2004).

	Sources	Types of producers	
Energy sources	Sunlight	Phototroph	-
	Preformed molecules	Chemotroph	-
Carbon sources	Inorganic compounds	-	Autotroph
	Organic compound	-	Heterotroph

Table 2 Organism can be classified by carbon nutrients (left column) and energy metabolism (top row) (Peters et al., 2004).

	Phototroph	Chemotroph
Autotroph	Photoautotroph	Chemoautotroph
	green-plant, bacteria, algae	nitrogen-fixing bacteria, iron bacteria, methanogen
Heterotroph	Photoheterotroph	Chemoheterotroph
	purple non-sulfur bacteria, green non-sulfur bacteria, and heliobacteria	fungi, lithotrophic bacteria

Consequently, chemical compositions or biomarkers that are specific component can be used in many fields, such as pharmacology, plant taxonomy, and further ecological or environmental reconstruction.

2.3.1 Biomarker for chemotaxonomy

The chemotaxonomy is the classification of plants based on their specific chemical constituents, which are produced from their biosynthetic pathways (Singh, 2016). The chemical constituents are often specific and limited to taxonomically related organisms and consequently useful in classification (Singh, 2016). In recent studies, chemical compositions of epicuticular wax from leaves have been widely used for chemotaxonomy (Pu et al., 2017).

Epicuticular waxes of higher plants are a first protective barrier to reduce the loss of water, reflect or attenuated ultraviolet radiation and control leaf temperature, and defend against attack by harmful pathogens (Peters et al., 2004). The most common epicuticular wax components are hydrocarbons, e.g. wax esters, fatty acids and fatty alcohols, ketones, primary alcohols, diols, and aldehydes (Herbin and Robins, 1969; Kolattukudy, 1970; Singh, 2016; Zeisler-Diehl et al., 2018). Aliphatic hydrocarbon have been widely used for chemotaxonomy, particular *n*-alkanes (Bush

and McInerney, 2013; Nikolić et al., 2013; Phountong, 2016) because they are widespread in cuticular waxes of higher plants, and easier to analyze than others (Eglinton and Hamilton, 1967) and further they can be used to apply in many fields e.g. paleoenvironment (Andersson et al., 2011; Meyers, 1997, 2003; Ratnayake et al., 2017), and air pollutant studies (Percy et al., 2009).

The *n*-alkanes of epicuticular wax are a mixture of straight-chain hydrocarbons consists of major carbon atoms (C_{21} - C_{37}), especially C_{29} and C_{31} and minor carbon atoms (C_{20} - C_{34}) (Eglinton and Hamilton, 1967; Herbin and Robins, 1969; Kuhn et al., 2010; Rao et al., 2011). They are usually synthesized from elongated fatty acid precursors by decarbonylation pathway (Fig 7) (Guo et al., 2014; Kolattukudy, 1970; Kunst and Samuels, 2003). The *n*-alkanes have been proposed to serve as a chemotaxonomy index among different plant types, mostly at the genus and species levels (Nikolić et al., 2013).

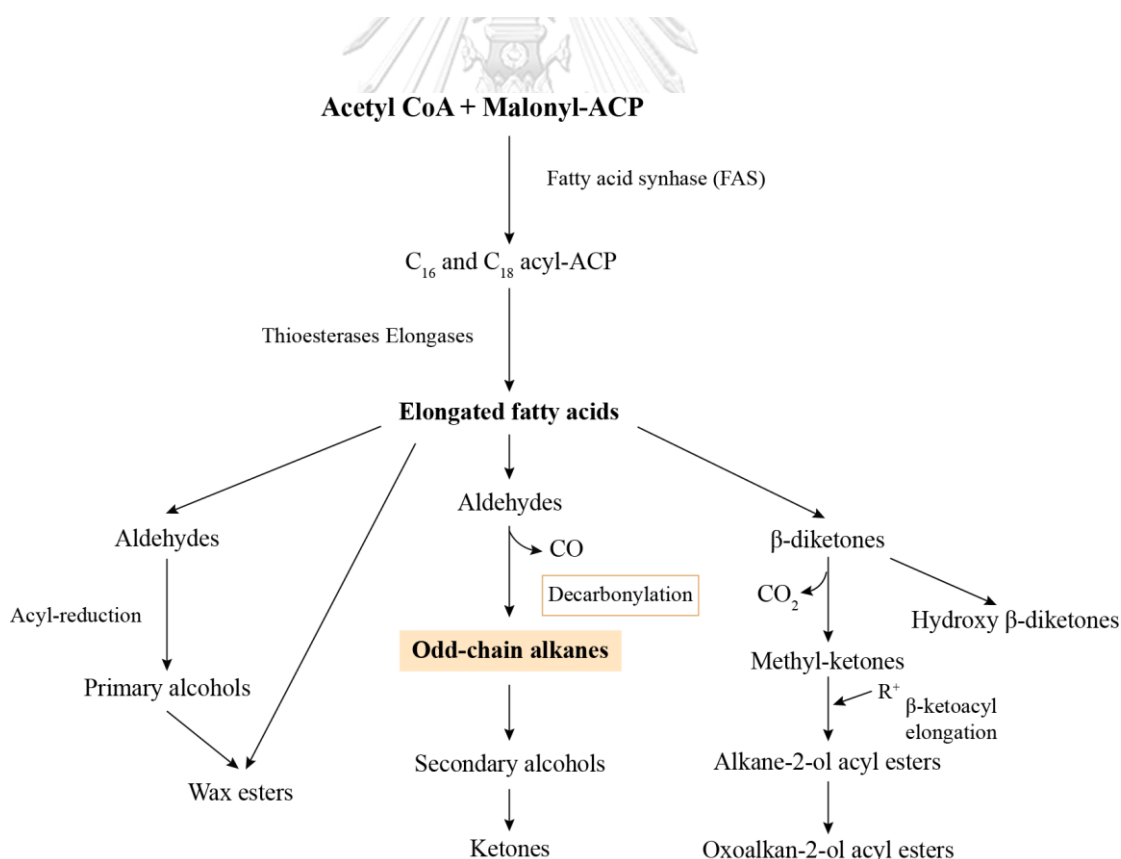

Figure 7 Biosynthetic pathway of epicuticular waxes. Odd-chain alkanes derived from decarbonylation by their biosynthetic pathway (Peters et al., 2004).

The epicuticular waxes of the higher plants generally consist of a long-chain *n*-alkanes range from C₂₁ to C₃₅ with the predominance of odd carbon number (Zeisler-Diehl et al., 2018). The shorter-chain *n*-alkanes lengths are mostly produced by other organisms. C₁₇ or C₁₉, for example, are produced by aquatic algae and photosynthetic bacteria (Cranwell, 1973). C₂₇, C₂₉, and C₃₁ *n*-alkanes are commonly originated by terrestrial plant epicuticular waxes (Cranwell, 1973; Meyers, 1997), and in particular, C₃₁ can be used to separate grasses from other land plants.

However, recent studies suggest more complication in the chemotaxonomy based on *n*-alkanes. Angiosperms, for example, generally synthesize more *n*-alkane than gymnosperms (Bush and McInerney, 2013). C₂₃ and C₂₅ are representative of *Sphagnum* mosses (Bush and McInerney, 2013). However, C₂₃ is the most abundant *n*-alkanes in the leaves of *Salix oritrepha*, which is a deciduous shrub. And C₂₅ has been found in the highest concentration in *Ajuga ovalifolia*, which is herb and submerged and floating aquatic plants (Ficken et al., 2000; Pu et al., 2017). The recent studies also indicate that woody plants cannot be distinguished from graminoids by *n*-alkane abundances because both groups are dominated by all C₂₇, C₂₉, and C₃₁ (Bush and McInerney, 2013). C₂₇, C₂₉, and C₃₁ are common in herb and shrub (Bush and McInerney, 2013; Vogts et al., 2009). However, this result was argued by Rao et al. (2010) that similar *n*-alkane distribution patterns do not contain a clear specific pattern among grasses, shrubs, and trees. The *n*-alkane ratio, e.g. average chain length (ACL), carbon preferent index (CPI), and proportion of aquatic plant (P_{aq}) were subsequently introduced to classify vegetation types in several studies (Bush and McInerney, 2013; Ficken et al., 2000; Pu et al., 2017).

ACL is an average value of *n*-alkane chain length that is a specific character in the higher plants (Bush and McInerney, 2013; Ficken et al., 2000; Pu et al., 2017). They show the significant difference among the same plant genera (Li et al., 2013). The CPI is a ratio of odd and even carbon chain length and generally high and wide range of CPI values are always found in the modern plant (Bush and McInerney, 2013; Li et al., 2013). Because aquatic plants commonly synthesize middle-chain *n*-alkane, the separation between macrophytes and land plants are simple. P_{aq} is a ratio of middle- and long-chain that is a potential proxy for aquatic plant separation (Ficken et al., 2000).

Many studies, however, proposed that the environmental conditions play a key role on the relative concentrations of hydrocarbon in the plants (Andersson et al., 2011; Baker, 1974; Guo et al., 2014; Herbin and Robins, 1969; Pitty, 1988). The environmental effect on epicuticular waxes has been investigated and reported that the production of waxes both their chemical contents and quantity are controlled by radiation, photoperiod, air temperature, moisture stress, relative humidity, or even leaf age (Norström et al., 2017; Pitty, 1988). For example, the production of epicuticular waxes in Brussel sprouts (*Brassica oleracea*) is mainly controlled by solar radiation (Baker, 1974). Ketone can be formed in Brussel sprouts when solar radiation is 80 W/m² (Baker, 1974). The same plant, however, produces alkane, if they receive the solar radiation of about 38 W/m². In contrast, the formation of epicuticular waxes in tobacco have been not related to radiation but depends on photoperiods (Wilkinson, 1972). C₃₁ in epicuticular waxes of tobacco increase from 4.5% to 11.7% of the total hydrocarbons, when decreasing the photoperiods from 16 to 12 hours (Wilkinson, 1972). In addition, the barley leaves grown under light can produce C₂₉, C₃₁, and C₃₃ summing 64% of the total hydrocarbons. But the hydrocarbon chain length becomes predominance of C₂₁, C₂₃, and C₂₅, which is about 46% of the total hydrocarbons, in the leave grown in dark (Wilkinson, 1974). Baker (1974) also suggested the influence of temperature on the epicuticular waxes that the plant growing at 15°C can produce a higher concentration of alkanes than that at 35°C. Hogg (1984) suggested that portion of hydrocarbons and fatty acids from a leaf of true mangrove plant are potentially reflected their environment. In contrast, the average chain length (ACL) values do not significant differences in both angiosperms and gymnosperms that are growing under the sun and shade, or in summer and fall (Bush and McInerney, 2013).

2.3.2 Biomarker for environmental reconstruction

The detritus of plants that grow in and around the lake are major sources of organic matter in the sediments (Meyers, 2003; Pu et al., 2017). Therefore, the aliphatic hydrocarbon in sediment is widely used for environmental reconstruction, especially *n*-alkanes compositions because of their high resistance to microbial degradation after sedimentation (Meyers and Ishiwatari, 1993).

The *n*-alkane can be used to assess the source of organic matter. For example, the short-chain *n*-alkanes, which commonly have a major component at C₁₇, C₁₅ or C₁₃, derived from algae and bacteria (Gelpi et al., 1970; Han et al., 1968). However, the long-chain *n*-alkane, which generally compose of C₂₇, C₂₉ or C₃₁, are mainly derived from higher plants (Cranwell, 1973; Eglinton and Hamilton, 1967; Han et al., 1968; Meyers, 1997, 2003; Meyers and Ishiwatari, 1993). Floating and submerged plants contain a broad range of *n*-alkanes from C₁₃ to C₃₁. The floating plants are dominated by C₂₅ or C₂₇ (Nishimoto, 1974), while C₁₉ or C₂₁ or C₂₅ are predominances in the submerged plants (Ficken et al., 2000).

In addition, *n*-alkane ratios, which are including average chain length (ACL), the carbon preference index (CPI), and the proportion of aquatic components (P_{aq}), have been further proposed in order to classify the provenance of organic matter. The ACL values are generally an indicator of organic matter input derived from diverse organisms, i.e. phytoplankton, aquatic plant, and terrestrial plant, in the sediments (Bush and McInerney, 2013; Ficken et al., 2000; Meyers, 2003; Zhang et al., 2017). Alternatively, ACL values had been used as paleohydrology proxy in Arctic bog (Andersson et al., 2011).

The *n*-alkanes found in sediment are not only abundance of the odd carbon number but also those of the even carbon number can be predominance (Kuhn et al., 2010; Nishimura and Baker, 1986). The CPI values are the relationship between odd and even carbon number that is usually used to assess even over odd carbon number predominance (EOP) and odd over even carbon number predominance (OEP) (Marzi et al., 1993). Since EOP is depended on the degree of maturity of source rocks and degradation level of sediment, this value is commonly used in petroleum geochemistry in order to estimate (Eglinton and Hamilton, 1967). However, the *n*-alkane distributions with a remarkable EOP (C₁₆ – C₂₄) were found in surface marine sediment that is possibly directly obtained from marine bacteria (Nishimura et al., 1985). Wang et al (2010) reported that the *n*-alkane from Linxia Basin showed a bimodal distribution which the *n*-alkanes is characterized by a range from C₁₆ – C₂₀ in a short-chain length, while a long-chain length is dominated by range from C₂₇ – C₃₁. Autochthonous bacteria are also a possible provenance of EOP because of a high production rate under arid deposition environment.

P_{aq} was frequently applied to the study of sediment. The relative proportion of middle-chain length (C_{23} , C_{25}) to long-chain length (C_{29} , C_{31}) can be used to separate submerge/floating plant from emergent and terrestrial plant (Ficken et al., 2000). High P_{aq} indicates freshwater swamp or lake environment. Anderson et al (2011) applied P_{aq} values that have been used to indicator for the water level in a peat bog.

As the mention to the *n*-alkanes in lake sediment derived from multiple inputs and consequently are likely to reflect different aspects of past environmental conditions. Hence, consideration of the possible origins has to rely on various potential biomarkers to expand and refine paleoenvironmental reconstructions.

2.4 Gas chromatography-mass spectrum technique

Gas chromatography-mass spectrum technique (GCMS) can be utilized to detect and identify compounds by relative gas chromatographic retention times, and the mass spectral fragmentation patterns characteristic of their structures.

A known amount of the hydrocarbon fraction was injected into the gas chromatograph. The injection was selected to split, split-less, solvent-split, or direct injection mode. The selection of the injection mode is depended on the portion and concentration of the sample. Each injected sample is vaporized and mixed with an inert carrier gas, such as helium or hydrogen. The vaporized mixture of sample and carrier gas then moves through a capillary column. The temperature of the column is raised gradually using a temperature-programmed oven. The gas (mobile phase) and sample mixture move through a long, thin capillary column (typically 0.20–0.25mm ID, 30–60m long) which inner surface is coated with a film (~0.25 μm thick) of non-volatile liquid (stationary phase). Different components were separated during their moving down in the column. They are repeatedly retained by the stationary phase and released into the mobile phase depend on their volatility and affinity for each phase.

The separated compounds were eluted and directly pass to the ionizing chamber in the mass spectrometer. At this point, the electron impact mode was selected for the ionization in GCMS. Most mass spectrometry systems ionize the eluting compounds in the electron-impact mode using 70 eV since molecules are ionized most efficiently in the range 50–90 eV based on the empirical experiment.

Then fragment ions generated in the ion source chamber are accelerated toward the detector through the mass analyzer by a high differential voltage. Ions formed in the source of the mass spectrometer are analyzed according to their mass/charge ratio using a magnetic or quadrupole mass spectrometer. An electron multiplier detects positive ions. Mass analyzer can be analyzed ion beam by two principle methods including magnets and quadrupole rods. But here only mention to quadrupole. Single or triple quadrupole and three-dimensional ion trap instruments all make use of quadrupole radio frequency (RF)/electrical fields to select ions of a given mass/charge ratio. Quadrupole mass filters use no focusing at all but achieve mass selection because, for a given set of conditions, only ions with a narrow range of mass/charge ratios are able to remain within the instrument during mass analysis. The only those ions of interest are trapped and detected.

Figure 8 A typical gas chromatograph/mass spectrometer performs six functions (from left to right): (1) compound separation by gas chromatography; (2) transfer of separated compounds to the ionizing chamber of the mass spectrometer; (3) ionization and acceleration of the compounds down the flight tube; (4) mass analysis of the ions; (5) detection of the focused ions by the electron multiplier; and (6) acquisition, processing, and display of the data by computer. Modified from (Peters et al., 2004).

CHAPTER III METHODOLOGY

The leaves of modern plants and lake sediments were collected in order to analyze *n*-alkanes and subsequently reconstruct the paleoenvironment in the study area. The method of study consists of sample collection and preparation, lipid extraction and purification, and eventually biomarker analysis by using gas chromatography-mass spectrometry (GC/MS) technique (Fig 8).

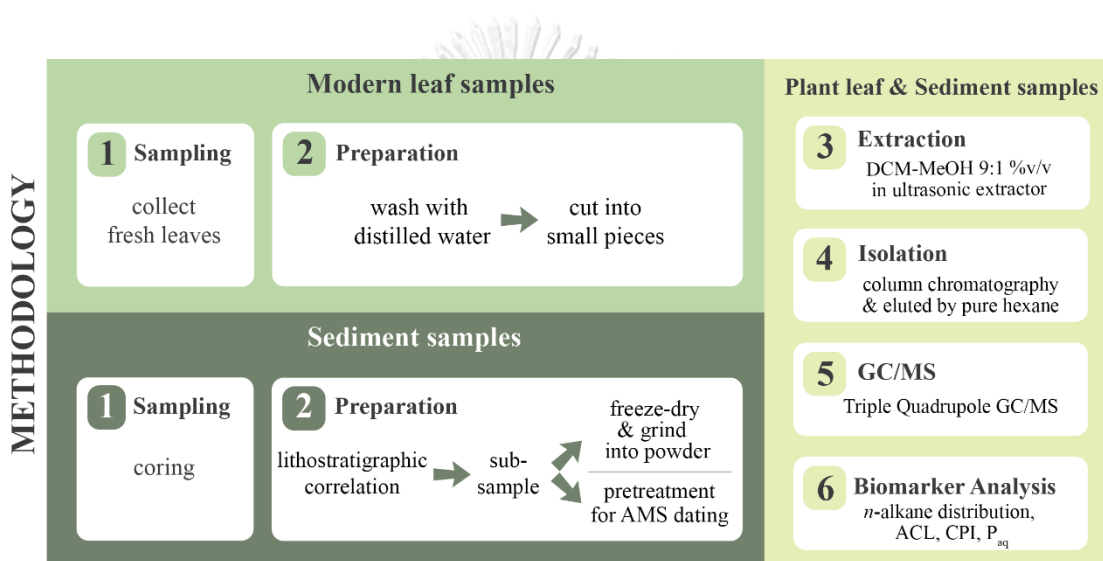

Figure 9 Diagram of the methodological procedure.

3.1 Sample collection and preparation

The leaf and sediment samples were taken in this study (Fig. 10).

3.1.1 Modern leaf samples

The leaves of modern plants from different environments were collected in regarding to pollen analysis in core TLN-CP5 between January and March in 2018 (Nudnara, 2016). The leaves of true mangrove and back mangrove plants were taken from Kung Krabaen Bay Royal Development Study Center (KKB), Chantaburi Province, Khun Samut Chin Temple (KSC) and Pom Pra Chulachomklao (PPC),

Samut Prakan Province, and Thale Noi (TLN), Phattalung Province. The leaves of mangrove associate plants were obtained from KKB and TLN (Fig 10).

Figure 10 Location map of leaf sampling sites a) including Kung Krabaen Bay Royal Development Study Center (KKB), Chantaburi Province b) , Khun Samut Chin Temple (KSC) c) , Samut Prakan Province, and Thale Noi (TLN), Phattalung Province d).

The seventeen leaf samples here can be assigned to 11 families (Table 3). The leaves were collected from at least five different trees for each species in the same location (Bush and McInerney, 2013). Moreover, the samples of *Barringtonia asiatica*, *Casuarina equisetifolia*, *Rhizophora mucronate* and *Sonneratia caseolaris* were taken from different locations in order to validate the *n*-alkane analysis. The

samples were placed in zipped plastic bags and stored in the refrigerator at the Department of Geology, Chulalongkorn University before further analysis.

The samples were prepared by carefully clean several times with deionized water and then cut into small pieces by scissors.

Table 3 The leaf samples were collected from Khun Samut Chin Temple (KSC), Kung Krabaen Bay Royal Development Study Center (KKB), and Thale Noi (TLN) (Fig. 10).

Location	Species	Plant groups
KSC	<i>Acrostichum aureum</i>	Back mangrove
	<i>Avicennia marina</i>	True mangrove
	<i>Rhizophora apiculate</i>	True mangrove
	<i>Rhizophora mucronate</i>	True mangrove
	<i>Sesuvium portulacastrum</i>	True mangrove
	<i>Sonneratia caseolaris</i>	True mangrove
KKB	<i>Barringtonia asiatica</i>	True mangrove
	<i>Bruguiera gymnorrhiza</i>	True mangrove
	<i>Casuarina equisetifolia</i>	Mangrove associate
	<i>Oncosperma tigllarium</i>	Back mangrove
	<i>Rhizophora mucronate</i>	True mangrove
	<i>Xylocarpus granatum</i>	Back mangrove
TLN	<i>Barringtonia asiatica</i>	True mangrove
	<i>Casuarina equisetifolia</i>	Mangrove associate
	Poaceae (<i>Bambusoideae</i>)	Mangrove associate
	<i>Sonneratia caseolaris</i>	True mangrove

3.1.2 Sediment samples

Sediment cores were taken from eight locations in Thale Noi, Phatthalung Province during January 2016 by using a modified Russian corer (7.5 cm diameter, 1 m length). To achieve a continuous sequence, sediment cores were taken 50 cm overlapping at each coring site. The sediment cores were wrapped in plastic and

placed in PVC tubes for transport to the Department of Geology, Chulalongkorn University. The sediment samples were then described in detail, correlation, constructed the composited depth, sub-sample, and stored in a refrigerator until analyses (Fig. 4).

The lithostratigraphy of the sediment cores was described and correlated by Yoojam (2015). According to the lithostratigraphy, Thale Noi possibly consists of two sub-basins in the eastern and the western parts of the lake (Yoojam, 2015). This result agrees well with Chaimanee (1986) that point to the deposition under freshwater swamp and true mangrove environments in the west and east Thale Noi, respectively. Core TLN-CP5 and CP7 are the longest sediment sequences from the western and eastern sub-basins (Fig. 4). They possibly record the long-term variability of environmental changes in this lake.

Sediment cores were subsampled every 1 cm interval and these samples were selected every 10 cm for the biomarker analysis. The selected samples were freeze-dried at Department of Marine Science, Chulalongkorn University, and then grind for homogenization and increase their surface area for the lipid extraction.

Figure 11 Location of sediment cores sampling in Thale Noi, Phatthalung Province.

3.2 Lipid extraction and purification

The prepared samples were put in 20 ml of a mixture of dichloromethane and methanol (DCM-MeOH 9:1% v/v) and left them in the ultrasonic extractor for 10 minutes for the lipid extraction (Pu et al., 2017). This process was repeated for 3 times. The mixture of solvent and total lipid was then put together and then evaporated by rotary evaporator. The evaporation had been continued until approximately 2 ml of mixture remaining in the round bottom flask. These prepared samples were transferred to a glass vial and left them under room temperature till all solvent evaporates. The total lipid was left in a vial glass in this step.

The non-polar fraction was further separated from the total lipid by silica column chromatography. Silica gels were weighed 10 times higher than that of the total lipid weight (10X of total lipid weight) and loaded them in a glass column. The total lipid was transferred to the silica gel column by an autopipette. The non-polar or *n*-alkane fraction was eluted by three to four column volume of hexane. All fractions were again poured into the round bottom flask and evaporated by rotary evaporator before transferring to the glass vial. Finally, hexane/ethyl acetate (1:1 % v/v) was added to the *n*-alkane fraction and sent to Scientific and Technological Research Equipment Center (STREC), Chulalongkorn University for further analysis.

3.3 Gas chromatography-mass spectrum analysis

The *n*-alkane fractions were analyzed by gas chromatography-mass spectrometer (GC/MS) on Triple Quadrupole GC/MS (GC-QQQ) Agilent Technologies, equipped with Agilent 7633 ALS Autosampler at Scientific and Technological Research Equipment Centre (STREC), Chulalongkorn University.

The 1.2 μ l of samples were injected in the split mode and passed through HP-5ms column (30 m \times 0.25 mm i.d., film thickness 0.25 μ m) into the GC oven by helium, which is a carrier gas (Pu et al., 2017). The oven temperature was increased from 100 to 320°C with 11°C/min and hold at 100°C and 320°C for 4 and 12 min, respectively. The gas of *n*-alkane fraction was then transferred to an ion source which temperature was set at 280°C to emit electrons, and the 70eV electron impact mass

spectra were acquired over the mass per charge (m/z) scan ranged from 35 to 650 (Fig. 8).

The individual *n*-alkanes were identified by an external standard of the mass spectrum of C12-C40 alkane D.

3.4 Biomarker analysis

The *n*-alkanes ranging from C₁₅ to C₂₀, and from C₂₁ to C₃₅ were defined to the short- and long-chain *n*-alkanes (Pu et al., 2017). The relative abundances of *n*-alkanes were calculated from the peak area of chromatogram. The distributions of *n*-alkanes were here classified into three patterns; the predominance in long- and short-chain *n*-alkanes, and bimodal patterns. The predominance in long-chain (short-chain) *n*-alkanes is here referred to the summary of the abundant intensity of the long-chain *n*-alkanes is higher (less) than 60% of those in the short-chain *n*-alkanes. The bimodal distribution is classified when the concentration of the dominant *n*-alkanes ranging from C₁₅ to C₂₀ is almost the same as those ranging from C₂₁ to C₃₅. Since the short-chain *n*-alkanes are possibly produced by microbial activity, the long-chain *n*-alkanes were solely considered in the sediments (Hao et al., 2015; Pu et al., 2017).

Moreover, the ratio between relative abundances of *n*-alkanes, e.g. average chain length (ACL) and carbon preference index (CPI) was introduced in order to classify plants and assess the source of organic matter in the sediments.

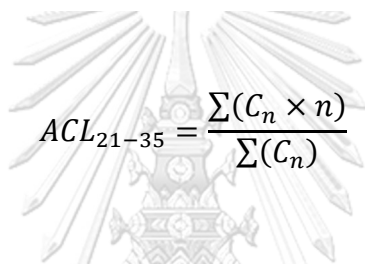

The ACL of hydrocarbon in leaf wax is a specific character in the individual plant species (Bush and McInerney, 2013; Ficken et al., 2000; Pu et al., 2017). The specific value of ACL makes it frequently used for a group of plant classification (Bush and McInerney, 2013). Moreover, the ACL is generally an indicator of organic matter input derived from diverse organisms such as phytoplankton, aquatic plant and terrestrial plant into the sediments (Bush and McInerney, 2013; Ficken et al., 2000; Meyers, 2003; Zhang et al., 2017).

The ACL was here calculated into two ranges; total average chain length (ACL_T) and average chain length of C₂₁ to C₃₅ (ACL₂₁₋₃₅) (Bush and McInerney, 2013). The plant group classification was referred from the ACL_T, which can be calculated by equation (1);

$$ACL_T = \frac{\sum(C_n \times n)}{\sum(C_n)} \quad (1)$$

Where C_n are the relative abundance of individual n -alkane from C_{15} to C_{35} and n are the number of carbon atoms (15-35), respectively.

Since the long-chain n -alkane is more resistance in microbial activity, the ACL_{21-35} was separated from ACL_T in order to assess the source of organic matter in the sediments (Bush and McInerney, 2013; Pu et al., 2017). ACL_{21-35} is weight mean of the carbon chain lengths from C_{21} to C_{35} that is generally used to assess the dominant proportions of n -alkanes chain length in the leaf waxes and sediments (Bush and McInerney, 2013; Pu et al., 2017). ACL_{21-35} can be calculated by equation (2);

$$ACL_{21-35} = \frac{\sum(C_n \times n)}{\sum(C_n)} \quad (2)$$

Where C_n are the relative abundance of individual n -alkane from C_{21} to C_{35} and n are the carbon atoms (21-35), respectively.

The ACL_{21-35} values in sediments and in leaf plants were compared in order to investigate the source of organic matter reflecting vegetation dynamics around the lake.

Carbon preference index (CPI) is the relationship between odd and even carbon number that is usually used to measure the relative abundance of odd to even carbon chain lengths (Marzi et al., 1993). This value is frequently used in petroleum geochemistry in order to estimate the degree of maturity of source rocks (Eglinton and Hamilton, 1967). The CPI in modern plants is mostly greater than 1 or odd over even predominance. However, even over odd predominance n -alkane can be produced under high degradation (Kuhn et al., 2010). Alternately, environmental conditions influence on the shift of n -alkane distribution (Herbin and Robins, 1969).

Here, we calculated two range of CPI that are CPI_T and CPI_{21-35} . The CPI_T is the ratio of odd over even carbon number chain length of C_{15} to C_{35} , which can be calculated by equation (3);

$$CPI_T = \frac{[\sum_{odd}(C_{15-33}) + \sum_{odd}(C_{17-35})]}{(2 \sum_{even} C_{16-34})} \quad (3)$$

Where C_{15-33} , C_{17-35} and C_{16-34} are the relative abundance of n -alkane between C_{15} and C_{33} , between C_{17} and C_{35} , and between C_{16} and C_{34} , respectively.

CPI_{21-35} is the ratio of odd over even carbon chain lengths of C_{21} to C_{35} (Marzi et al., 1993) that can be calculated by equation (4);

$$CPI_{21-35} = \frac{[\sum_{odd}(C_{21-33}) + \sum_{odd}(C_{23-35})]}{(2 \sum_{even} C_{22-34})} \quad (4)$$

Where C_{21-33} , C_{23-35} and C_{22-34} are the relative abundance of n -alkane between C_{21} and C_{33} , between C_{23} and C_{35} , and between C_{22} and C_{34} , respectively.

The CPI_{21-35} value in modern plants and sediments are further used to examine the relationship between organic matters in the lake and its surrounding plant. While Furthermore, low CPI_T also indicate the degree of organic origin decomposition and degradation.

Submerged/floating plants often create a middle-chain length of n -alkane in particularly between C_{23} and C_{25} (Ficken et al., 2000). This work P_{aq} was applied to the study of sediment samples followed Ficken (2000). The relative proportion of middle-chain length (C_{23} , C_{25}) to long-chain length (C_{29} , C_{31}) or proportion of aquatic components (P_{aq}) can be used to separate submerge/floating plant from emergent and terrestrial plant (Ficken et al., 2000). P_{aq} can be calculated by equation (5);

$$P_{aq} = \frac{C_{23} + C_{25}}{C_{23} + C_{25} + C_{29} + C_{31}} \quad (5)$$

P_{aq} are generally less than 0.1 in the terrestrial plants, while P_{aq} of 0.1 - 0.4 and 0.4 - 1 are reflecting emergent and submerged/floating macrophytes, respectively

(Ficken et al., 2000). Alternatively, the P_{aq} of 0.1 - 0.4 in sediment can be assessed to a mixture of inputs from terrestrial, emergent and submerged/floating aquatic macrophytes (Ficken et al., 2000). Furthermore, P_{aq} can also be used to estimate the n -alkane distribution, for example, P_{aq} less than 0.1 is related to long-chain predominance, 0.1 to 0.4 is related to middle-chain and long-chain predominance or bimodal distribution, and 0.4 to 1 is related to middle-chain predominance.

3.5 Radiocarbon dating and age-depth model

The sufficient age control is necessitated to insight into the regional environmental changes. Among various dating techniques, the radiocarbon is possibly the most widely used to construct a chronology of the lake sediments. However, the pretreatment of dating sample is necessary in order to reduce any sources of error (Björk and Wohlfarth, 2001).

The selected sediment samples were deflocculation by 5% sodium hexametaphosphate or Calgon. The deflocculated samples were then sieved under running water with a mesh size of 500 μm . The sieved plant remains were identified under a stereomicroscope. Plant roots were excluded but leaves, teak, charcoal, and seed were here selected. The selected samples were cleaned several times by distilled water and then dried in an oven at 60°C for overnight. After that, the dried samples were treated by acid-base-acid technique (ABA) (Brock et al., 2010). A 1 M hydrochloric acid (HCl) was added and put the samples in an oven at 80°C for 20 minutes in order to eliminate the carbonate content. After that, the samples were rinsed by distilling water 3 times. To remove organic acids such as humic and fulvic acid, the sample was then treated by a 0.2 M sodium hydroxide (NaOH) and put them in an oven at 80°C for 20 minutes. The sample was subsequently cleaned 3 times by the distilled water. The 1 M HCl was again added to the treated samples and put them in an oven at 80°C for 1 hour in order to eliminate the dissolved atmospheric CO₂ and then washed them by the distilled water 3 times. The samples were dried in an oven at 60°C for an overnight before putting them in the glass vials and eventually sending to Direct AMS for the radiocarbon dating. The radiocarbon dating results were calibrated by using InCal13 (Reimer et al., 2013), and the age-depth models were

subsequently constructed by using computer software called BACON (the Bayesian accumulation histories of deposits) (Blaauw and Christen, 2011).

An age-depth model of sediment TLN-CP5 core was constructed by Phountong (2016) based on nine C-14 dating results (Table 7). The age of sediment sequence TLN-CP5 extends from 8300 to 7200 cal yr. BP. The detailed chronology of core TLN-CP5 will be present in the discussion. Furthermore, four samples from TLN-CP7 core were sent to analyze the radiocarbon dating. However, there are only two samples were used for the construction of chronology for core TLN-CP7. These new results were also presented in detail in Chapter 4.

CHAPTER IV RESULTS

The results were here divided into 3 parts including *n*-alkane analyses in the modern leaf waxes, and in the sediments from core TLN-CP5 and TLN-CP7 (Fig. 11).

4.1 The *n*-alkane analysis in the modern leaf waxes

The modern leaf samples were taken in regarding to pollen analysis by Nudnara (2017) that compose of true mangrove, back mangrove and mangrove associate from Kung Krabaen Bay Royal Development Study Center (KKB), Chantaburi Province, Khun Samut Chin Temple (KSC) and Pom Pra Chulachomklao (PPC), Samut Prakan Province, and Thale Noi (TLN), Phattalung Province (Fig. 10). The *n*-alkanes analysis in the modern leaf wax was further compared with these in the sediment sequence from Thale Noi, Phattalung Province in order to insight into the past environmental changes.

True mangrove plants

True mangrove plants are vegetation growing in tidal environments or the brackish environment (Tomlinson, 1986; Duke, 1992; Giesen et al., 2007). The modern leaf samples of mangrove plants were here collected from KKB, KSC and PPC, and TLN that consisted of *Avicennia marina*, *Barringtonia asiatica*, *Bruguiera gymnorhiza*, *Rhizophora apiculata*, *Rhizophora mucronate*, *Sesuvium portulacastrum*, and *Sonneratia caseolaris*.

Avicennia marina, *Rhizophora apiculata* and *Sonneratia caseolaris* are the predominances in the long-chain *n*-alkanes (Fig. 12). C₃₃ and C₃₁ are the highest concentration of about 45% in *Avicennia marina*, and 40% in *Rhizophora apiculata*. However, C₃₁ is the most abundant of 40% in *Sonneratia caseolaris* from KSC but C₃₃ is about 30% and more dominant in this kind of plant from TLN. The short-chain *n*-alkanes are generally less than 5% in *Avicennia marina*, *Rhizophora apiculata* and *Sonneratia caseolaris*.

Figure 12 The predominance of long-chain *n*-alkane in true mangrove plants consisting of *Avicennia marina*, *Rhizophora apiculata* and *Sonneratia caseolaris*.

The predominance in the short-chain *n*-alkanes can be found in the sample of *Bruguiera gymnorrhiza* and *Sesuvium portulacastrum* (Fig. 13). The long-chain *n*-alkanes abundances are lower than 5% in *Sesuvium portulacastrum* and *Bruguiera gymnorrhiza*. C₁₆ are the most abundant *n*-alkanes in *Sesuvium portulacastrum* and *Bruguiera gymnorrhiza* that their concentrations are approximately 20%.

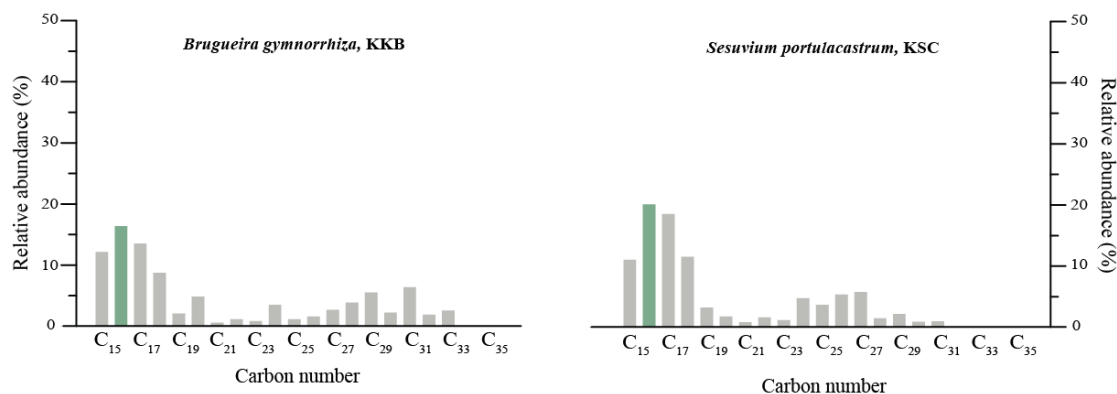

Figure 13 The predominance of short-chain *n*-alkane in true mangrove plants consisting of *Bruguiera gymnorrhiza* and *Sesuvium portulacastrum*.

Interestingly, the, unlike *n*-alkanes distribution, can be found in *Rhizophora mucronate* and *Barringtonia asiatica* from different sites. C₂₉ is the most abundant of more than 50% in *Rhizophora mucronate* from KSC (Fig. 14). The short-chain *n*-alkanes have been found in a low concentration of less than 5% in this sample. However, C₂₉ and other long-chain *n*-alkanes become less than 10% in *Rhizophora mucronate* from KKB. The most predominate *n*-alkane in the *Rhizophora mucronate* from KKB is C₁₇, which is approximately 19%. The *n*-alkanes distribution of *Rhizophora mucronate* from KSC and KKB can be classified to the predominance of long- and short-chain *n*-alkanes, respectively (Fig. 14).

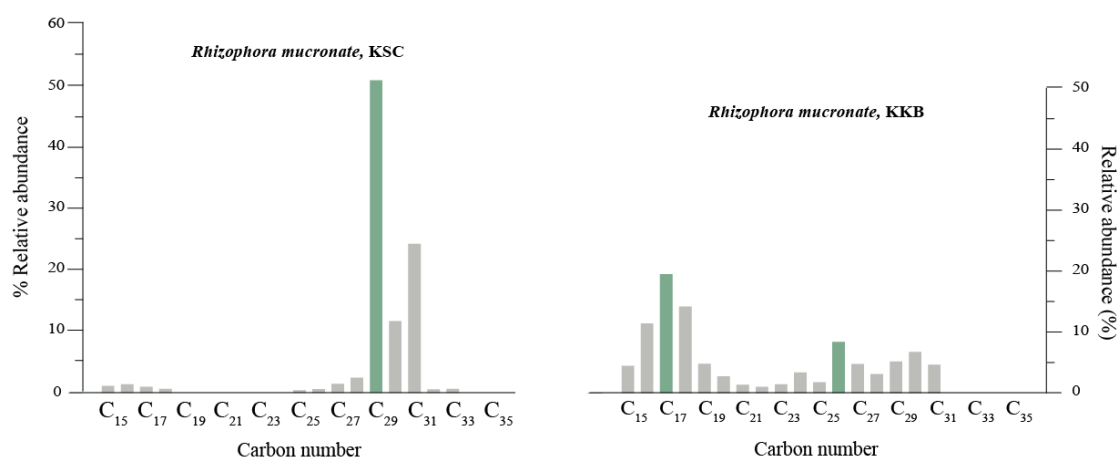

Figure 14 The predominance of long-chain *n*-alkanes in *Rhizophora mucronate* from KSC (left) and the bimodal distribution of *n*-alkanes *Rhizophora mucronate* from KKB (right).

The different pattern of *n*-alkanes distribution can be also found in *Barringtonia asiatica*. The sample from TLN is the predominance in the short-chain *n*-alkanes (Fig. 15), while the bimodal distribution is in the samples from KKB (Fig. 15). C₁₇ and C₁₈ are the most abundant short-chain *n*-alkanes of about 18% in the *Barringtonia asiatica* from TLN. The *n*-alkanes ranging from C₂₁ to C₃₁ have been found only less than 10% in this sample. C₁₆ and C₂₄ are about 10% and 15% and they are the highest concentration of the short- and long-chain *n*-alkanes in *Barringtonia asiatica* from KKB.

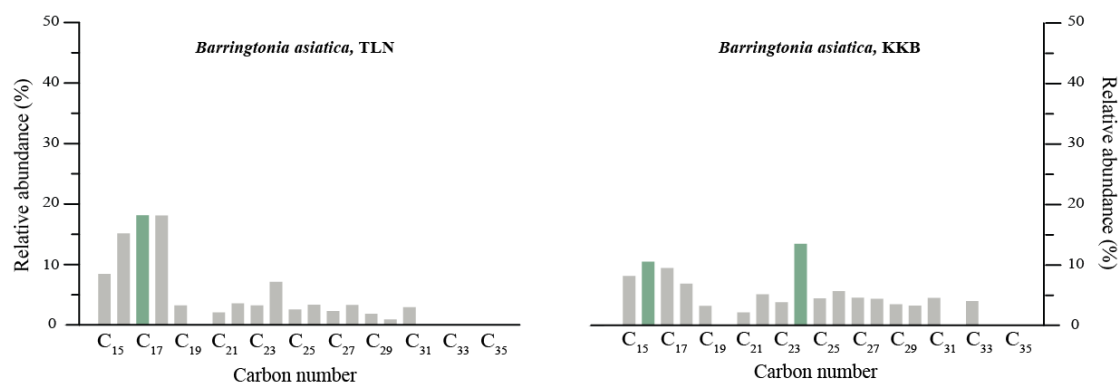

Figure 15 The *n*-alkanes distribution in *Barringtonia asiatica* from TLN is the predominance in the short-chain *n*-alkanes (left), while the bimodal distribution is in the samples from KKB (right).

The ACL_T and ACL₂₁₋₃₅ values are varied from 19.55 to 31.90, and from 26 to 32 (Table 4). According to the ACL_T, the mangrove plants are generally dominated by the long-chain *n*-alkanes. The exceptions are *Sesuvium portulacastrum* from KSC and *Barringtonia asiatica* from TLN that is prevailed by the short-chain *n*-alkane (Table 4).

The CPI_T and CPI₂₁₋₃₅ values are ranged from 0.79 to 11.30, and from 0.76 to 15.29 (Table 4). According to the CPI_T, *Avicennia marina*, *Rhizophora apiculate*, and *Sonneratia caseolaris* can be assigned to the odd over even predominance (Table 4). The CPI_T values are less than 1 in the modern leaf samples of *Barringtonia asiatica*, *Bruguiera gymnorrhiza*, and *Sesuvium portulacastrum*. CPI_T of *Rhizophora mucronate* however is higher than 1 in the sample from KSC, while the value became less than 1 in the sample from KKB (Table 4). The classification of odd over even or

even over odd predominance based on CPI_{21-35} is generally similar to those in regarding to CPI_T . However, *Bruguiera gymnorrhiza* and *Sesuvium portulacastrum* can be assigned to odd over even predominance based on CPI_{21-35} (Table 4).

Back mangrove

The back mangrove plants are the plant community that is located landward next to true mangrove. These plants can be distinguished from true mangrove vegetation by their appearance in peripheral mangrove habitats (Berlyn, 1986). The modern leaf samples of back mangrove plants consisting of *Acrostichum aureum*, *Oncusperma tigllarium*, and *Xylocarpus granatum* were collected from KKB and KSC.

The long-chain *n*-alkanes are predominated in the *Acrostichum aureum*, but *Oncusperma tigllarium* and *Xylocarpus granatum* are dominated by the short-chain *n*-alkanes (Fig. 16, 17). C_{33} is the most abundant of more than 40% in *Acrostichum aureum* while the short-chain *n*-alkane are generally less than 10% (Fig. 16). C_{17} is about 20%, which is the most abundant in *Oncusperma tigllarium*. However, the most dominant *n*-alkanes in *Xylocarpus granatum* is C_{17} , which is approximately 20%. In *Oncusperma tigllarium* and *Xylocarpus granatum*, the short-chain *n*-alkanes have been found in a low concentration of less than 5% (Fig. 17).

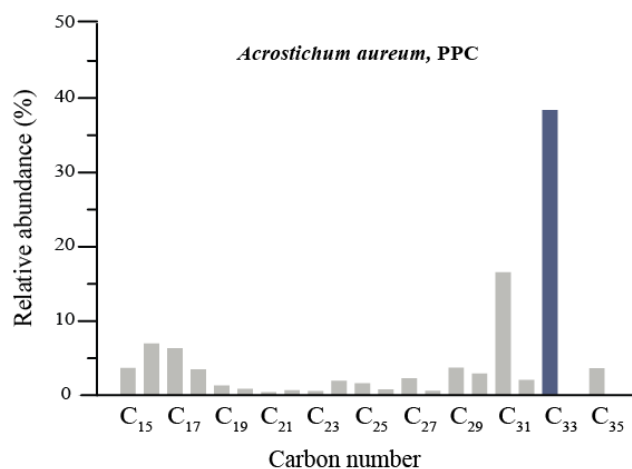

Figure 16 The predominance of long-chain *n*-alkanes in *Acrostichum aureum*.

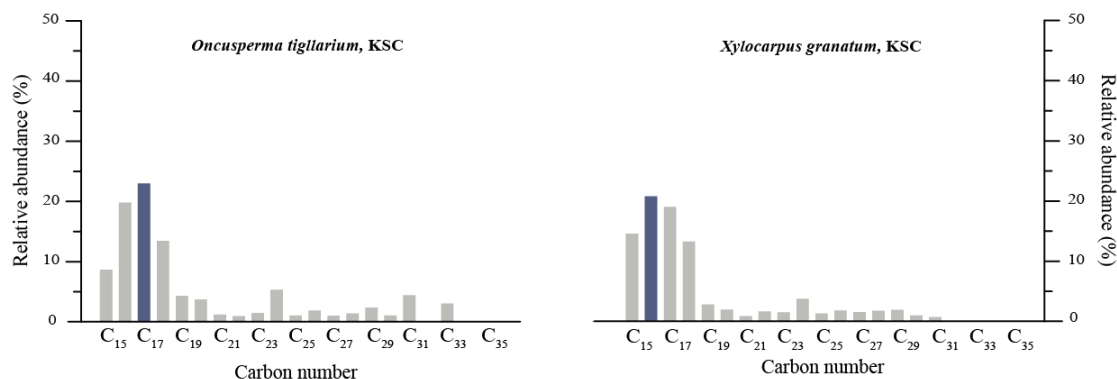

Figure 17 The predominance of short-chain *n*-alkanes in *Oncusperma tigllarium* (left) and *Xylocarpus granatum* (right).

ACL_T are about 29.63, 20.21 and 18.10 in *Acrostichum aureum*, *Oncusperma tigllarium*, and *Xylocarpus granatum*, respectively (Table 4). The ACL_T in *Oncusperma tigllarium*, and *Xylocarpus granatum* show the short-chain predominance that agrees well with the distribution of *n*-alkanes (Fig. 17). The ACL₂₁₋₃₅ in *Acrostichum aureum*, *Oncusperma tigllarium*, and *Xylocarpus granatum* are 31.63, 28.74 and 26.10, respectively (Table 4).

According to the CPI_T values, *Acrostichum aureum* can be classified to odd over even predominance, but *Oncusperma tigllarium* and *Xylocarpus granatum* are even over odd predominance (Table 4). However, *Oncusperma tigllarium* can be recognized as the odd over even predominance based on CPI₂₁₋₃₅ (Table 4).

CHULALONGKORN UNIVERSITY

Mangrove associate

The mangrove associate is vegetation that is mainly distributed in a terrestrial or aquatic habitat but also occurs in the mangrove ecosystem. The mangrove associate here consists of *Casuarina equisetifolia* and Poaceae (*Bambusoideae*).

The distribution of *n*-alkanes in Poaceae (*Bambusoideae*) demonstrates the predominance in long-chain *n*-alkanes, which C₃₃ concentration is about 25% (Fig. 18). The highest concentration of the short-chain *n*-alkanes in this plant is C₁₇ that is about 10%. The predominance in short-chain *n*-alkane and the bimodal distribution can be found in *Casuarina equisetifolia* from KKB and TLN, respectively. C₁₆ and C₂₄ are the most abundant short- and long-chain *n*-alkanes in *Casuarina equisetifolia*

from KKB that is about 20 and 5%, respectively. However, *Casuarina equisetifolia* from TLN is mainly consisted of C₁₈ and C₂₄ which their concentration are approximately 15 and 10% (Fig. 19).

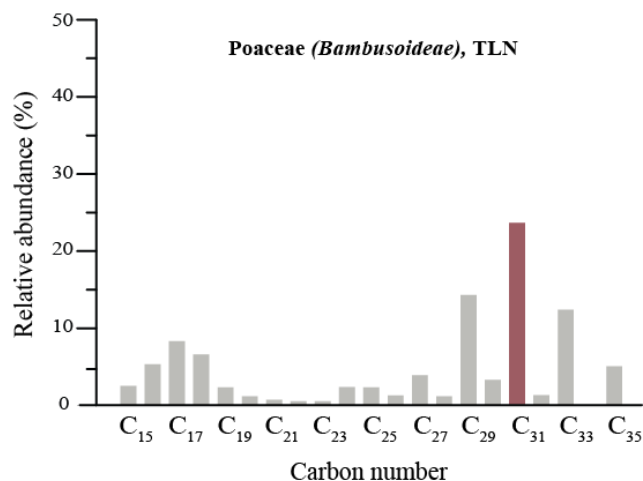

Figure 18 The predominance of long-chain *n*-alkanes in Poaceae (*Bambusoideae*).

Figure 19 The predominance of short-chain *n*-alkanes in *Casuarina equisetifolia* from KKB (left) and a bimodal distribution of *n*-alkanes in *Casuarina equisetifolia* from TLN (right).

The distribution of *n*-alkane in the same kind of plant species (*Casuarina equisetifolia*) from different sites (from KKB and TLN, respectively).

The ACL_T in *Casuarina equisetifolia* from KKB and TLN are 18.22 and 21.60 that suggest the short-chain *n*-alkane predominance (Table 4). However, ACL_T is about 28.24 in Poaceae (*Bambusoideae*) that is prevailed by the long-chain *n*-alkane (Table 4).

CPI_T and CPI_{21-35} of *Casuarina equisetifolia* are between 0.6 and 0.7 that can be classified to the even over odd predominance (Table 4.1). However, CPI_T and CPI_{21-35} of Poaceae (*Bambusoideae*) are 3.14 and 6.04 which indicate the odd over even predominance group (Table 4).

Table 4 Biomarker values of modern plants divide into three groups consist of true mangrove, back mangrove, and mangrove associate. LOQ = ppt

^c $CPI_T = (C_{15} + C_{17} + \dots + C_{33}) + (C_{17} + C_{19} + \dots + C_{35}) / 2(C_{16} + C_{18} + \dots + C_{34})$

^d $CPI_{21-35} = (C_{21} + C_{23} + \dots + C_{33}) + (C_{23} + C_{25} + \dots + C_{35}) / 2(C_{22} + C_{24} + \dots + C_{34})$

4.2 The *n*-Alkane analysis in sediments from TLN-CP5

The sediment sequence TLN-CP5 was described in detail by Yoojam (2015) based on Wohlfarth (2012) classification. The TLN-CP5 core can be divided into five sediment units (Fig 20). The basal unit is the stiff light gray clay of unit A (385.0 – 368.0 cm depth below water surface), which is overlaid by the dark grey clay of unit B (368.0 – 333.5 cm depth below water surface). The sediment unit B gradually transfers to peat layer of unit C (333.5 – 289.5 cm depth below water surface). The sharp boundary can be observed between the top of the peat layer and bottom of dark grey clay with detrital organic matter of unit D (289.5 – 217 cm depth below water surface). The uppermost unit E (217 – 150 cm depth below water surface) is the dark gray to dark brown sediments called gyttja. Since the short-chain is possibly decomposed by microbial activities, the *n*-alkanes analysis in sediments has been here considered from C₂₁ to C₃₅ (Bush and McInerney, 2013). The lithostratigraphic column of core TLN-CP5 was further compared with the distribution of *n*-alkane, ACL₂₁₋₃₅, CPI₂₁₋₃₅, and P_{aq} for the past environmental reconstruction.

Table 5 Lithostratigraphic description of TLN-CP5 sediment core (Yoojam, 2015).

Depth below water surface (cm)	Lithostratigraphic description	Layers	Units
168.0 – 150.0	Dark brown gyttja	20	E
179.5 – 168.0	Dark brown clayey gyttja	19	E
182.0 – 179.5	Dark brown gyttja	18	E
205.0 – 32.0	Dark brown clayey gyttja	17	E
209.0 – 205.0	Dark brown gyttja	16	E
217.0 – 209.0	Dark brown clayey gyttja	15	E
227.5 – 217.0	Dark grey clay	14	D
248.0 – 227.5	Grey clay	13	D
264.0 – 248.0	Dark grey clay	12	D
278.0 – 264.0	Dark grey clay with detrital organic matter	11	D
286.0 – 278.0	Dark grey clay	10	D
298.5 – 286.0	Dark grey clay with detrital organic matter	9	D
298.5	Possibly hiatus		
308.5 – 298.5	Peat	8	C
311.0 – 308.5	Peaty clay	7	C
333.5 – 311.0	Peat	6	C
340.5 – 333.5	Dark grey clay	5	B
344.0 – 340.5	Peat	4	B
350.5 – 344.0	Dark grey clay	3	B
368.0 – 350.5	Dark grey clay with detrital organic matter, found the root.	2	B
385.0 – 368.0	Stiff and light grey clay	1	A

Figure 20 Lithostratigraphy of core TLN-CP5 (Yoojam, 2015). The coring point is shown in figure 11.

4.2.1 Distributions of *n*-alkane in TLN-CP5

C_{28} is the most abundant *n*-alkanes of about 15% in the stiff light grey clay of unit A (Fig. 21). The predominant *n*-alkanes are diverse in sediment unit B, which consist of 4 layers (Fig. 22 and Table 4). C_{25} is the highest concentration in dark grey clay with detrital organic matter of layer 2. However, the dark grey clay of layer 3 and 5 are dominated by C_{29} and C_{31} . C_{25} , C_{29} , and C_{31} are about 15% at 360, 350 and 340 cm depth, respectively (Fig. 22). In the peat layer of unit C, C_{31} is the most abundance, especially at 320 and 310 cm depth, which its concentration is higher than 30% (Fig. 23). C_{31} is relatively less abundance than that at 320 and 310 cm depth

which is about 17.5% at 330 cm depth. However, the dominance of C₃₁ is replaced by C₂₇ in the uppermost peat layer (layer 8) at 300 cm depth. C₃₁ have been found only 10%, while the relative abundance of C₂₇ is about 15%.

For unit D, C₃₁ become again prevailing in the dark grey clay with detrital organic matter at 290 and 270 cm depth (layer 9 and 11) (Fig. 24, D-1), and in the dark grey at 280 cm depth (layer 10). However, the relative abundance of C₃₁ is less than that in unit C.

This layer is overlaid by the dark grey clay (layer 12 and 14) and grey clay (layer 13) layers (Table 5). C₂₁ is a dominance of about 20 and 15% at 260 and 250 cm depth in layer 12 (Fig. 25, D-2). It is also found in high concentration in the lower part of layer 11, while the upper part of layer 12 become predominance of C₂₆. The dark grey clay of layer 14 is dominated by C₃₁, which its abundance is about 20% (Fig. 26, D-3).

Unit E is dominated by C₃₁ from 210 to 200 cm depth, which relative abundance is approximately 20%. The predominance of C₃₁ was occupied by C₂₇ in the upper part of unit E from 190 to 155 cm depth. The concentration of C₂₇ is about 15%.

4.2.2 Average chain length, carbon preference index and proportion of aquatic macrophyte

The ACL_{21-35} values are varied from 25.0 to 30.0, respectively. Despite the ACL_{21-35} gradually increase from 26.0 to 28.0 in sediment unit A and C, The ACL_{21-35} generally decrease from 30.0 to 26.0 in from the bottom to middle of unit D before gradually increase to about 28.0 in the lowermost layer of unit E. The increases in ACL_{21-35} values are in the bottom to middle part of unit E. The ACL_{21-35} values are approximately 28.0 at the uppermost part of the sedimentary sequence (Fig. 28).

The variability of CPI_{21-35} relatively resembles with those in ACL_{21-35} . CPI_{21-35} varies from 1.0 to 3.0. CPI_{21-35} enhance from 1.0 to 3.0 in unit A and the middle part of unit C. CPI_{21-35} gradually decline from 3.0 to 1.0 in the upper part of unit C. It slightly changes of about 1.0 in unit D and the unit E (Fig. 28).

P_{aq} gradually decrease from 0.4 to 0.2 in unit A and lower part of unit C. It becomes increase from 0.2 to 0.4 at the upper layer of unit C and varies from 0.4 to 0.2 through unit D. A gradual increase in P_{aq} from 0.2 to 0.4 can be found in the lower part of unit E before it becomes an insignificant change in the upper part of this unit (Fig. 28).

Figure 28 Derived the *n*-alkane biomarker parameters ACL_{21-35} , CPI_{21-35} , and P_{aq} from core TLN-CP5 along with depth (cm).

4.3 The *n*-Alkane analysis in sediments from TLN-CP7

The sedimentary sequence of core TLN-CP7 core contains three sedimentary units which were described in detail by Yoojam (2015) (Table 6). The basal unit of the core is very similar to unit C in the TLN-CP5 core. But the peat in this unit is very well compaction and can be split into thin sheets. This unit, therefore, was distinguished and called unit C* (439.0 – 436.0 cm depth below water surface). The compacted peat was overlaid by grey clay with dark plant detritus of unit D (436 – 189 cm depth below water surface), which is the longest unit in this core. The uppermost unit E is gyttja (189 – 150 cm depth below water surface). The lithostratigraphic column of core TLN-CP7 was here compared with the *n*-alkane, ACL_{21-35} , CPI_{21-35} , and P_{aq} (Fig. 29).

Table 6 Lithostratigraphic description of TLN-CP7 sediment core (Yoojam, 2015).

Depth below water surface (cm)	Lithostratigraphic description	Layers	Units
162.0 – 150.0	Dark brown gyttja	18	E
168.0 – 162.0	Dark brown clayey gyttja	17	E
175.0 – 168.0	Dark brown gyttja	16	E
179.0 – 175.0	Dark brown clayey gyttja	15	E
182.0 – 179.0	Dark brown gyttja clay	14	E
189.0 – 182.0	Brown gyttja clay	13	E
195.0 – 189.0	Brown clay	12	D
200.0 – 195.0	Dark grey clay with detrital organic matter	11	D
277.0 – 200.0	Grey clay with detrital organic matter	10	D
233.0 – 277.0	Grey clay with detrital organic matter	9	D

Figure 29 Lithostratigraphy of core TLN-CP7 (Yoojam, 2015). The coring point is shown in figure 11.

4.3.1 Distributions of *n*-alkane in TLN-CP7

Samples at 437 cm depth below water surface were here selected to represent the compacted peat of unit C*. The most abundant *n*-alkane is C₂₉ (Fig 30).

The *n*-alkanes distribution in unit D, which is about 390 cm thick, are generally diverse. C₂₁ is the most dominant of higher than 15% in the sample at 433 and 430 cm depth below water surface (layer 1 and 3), which is the lowermost layer of unit D (Fig. 31). C₂₆ is the highest concentration of about 14% at 410 cm depth below water surface (layer 6).

At 380 cm depth below water surface (layer 7), the most abundant *n*-alkanes is C₂₄, which is about 17%. Notably, the relative abundance of C₂₁ is about 16%, which is slightly lower than C₂₄, in this sample. C₂₁ become the most dominant *n*-alkanes of about 17.5% in the samples at 360, 340 and 320 cm depth below water surface (layer 7).

For the middle part of unit D (unit D-2), C₂₆ is the most abundant about 12.5% in the light grey clay at 300 cm depth below water surface (Fig 32). C₂₆ is slightly less than C₂₉, which its abundance is about 12%, at 280 cm depth. It became again predominance at 260 cm depth below water surface that is about 12%. At 240 cm depth below water surface, the highest abundant *n*-alkanes is C₂₇, which is about 15%.

The dominant *n*-alkane the upper part of unit D (unit D-3) between 220 and 190 cm depth below water surface are different (Fig. 33; D-3). At 220 cm depth below water surface (layer 9) are the dark grey clay, which is dominated by C₂₉. Whereas the dark grey clay (layer 11) and the brown clay (layer 12) are dominated by C₂₆ and C₂₄, respectively.

The most abundant *n*-alkanes of unit E are C₂₉ (layer 14) and C₂₇, which are about 15% and 20% at 170 and 160 cm depth below water surface (layer 16 and 18) (Fig. 34).

4.3.2 Average chain length, carbon preference index and proportion of aquatic macrophyte

The ACL₂₁₋₃₅ values are varied from 26.0 to 28.5. The ACL₂₁₋₃₅ gradually decrease from 28.0 to 26.0 in the sediment unit *C and D between 430 and 320 cm depth below water surface. The ACL₂₁₋₃₅ in unit D between 300 and 190 cm depth below water surface increase from 26.0 to 28.0 before gradual decrease from 28.0 to 26.0 in unit E (Fig. 35).

The variability of CPI₂₁₋₃₅ varies from 0.8 to 4.8. The CPI₂₁₋₃₅ in the unit *C decrease from approximately 1 unit of the value and remained constant at approximately 1.0 in unit D and in the lowermost layer of unit E. The CPI₂₁₋₃₅ significantly increase in the uppermost layer of unit E that increase from about 1.0 reach to 3.2 (Fig. 35).

The P_{aq} values are varied from 0.2 to 0.7. The lowest P_{aq} is 0.2, which was found at 287 cm depth in the unit *C. Then it becomes increase and remained constant approximately 0.3 to 0.4 in unit D and the lower part of unit E. The P_{aq} in the upper part of unit E is remarkably increased. It becomes an increase from 0.4 to 7.0 (Fig. 35).

Figure 35 Derived the *n*-alkane biomarker parameters ACL₂₁₋₃₅, CPI₂₁₋₃₅, and P_{aq} from core TLN-CP7 along with depth (cm).

4.4 Chronology

The radiocarbon dating results were calibrated by InCal13 (Reimer et al., 2013) (Table 7 and Table 8), and then the age-depth models were constructed by BACON (the Bayesian accumulation histories of deposits) (Blaauw and Christen, 2011).

4.4.1 Chronology of TLN-CP5

Chronology of TLN-CP5 based on nine ^{14}C dates of plant remains (Table 7). The dated plant remains to provide ^{14}C age from 8,192 – 8,363 cal yr BP to recent.

The dating results of sample no. 021775, 021774, 021773 and 021776 in sediment unit A, B and C suggest that deposition occurs during 8,192 – 8,363 to 7,962 – 8,072 cal yr BP (Phountong, 2016). And show a gradual deposition of sediments from 368.0 to 298.5 cm depth below water surface. Interestingly, the different dating age between sample no. 021775 and 021776 are about 300 years. Consequently, the accumulation rate is approximately 0.20 cm/yr.

A boundary between unit C and D is sharp, which would suggest a rapid change during the deposition. Sample no. 021776 and 022510 were consequently taken from the top of unit C and bottom of unit D, which are about 7,962 – 8,072 and 7,566 – 7,669 cal yr BP, respectively (Phountong, 2016). The depth interval between no. 021776 and 022510 are approximately 7.5 cm and the different dating age between sample no. 021776 and 022510 are about 400 cal yr BP that suggest the low accumulation rate is approximately 0.02 cm/yr or the presence of a hiatus.

Sample no. 022509, 021777 and 021771 were taken from the middle of unit D, and the bottom and top of unit E, respectively. The dating of no. 022509 and 021777 are about 7,566 – 7,669 and 7,142 – 7,258 cal yr BP (Phountong, 2016). While sample no. 021771 shows a modern age. The dating of sample no. 022509 and 021777 shows a gradual deposition for about 400 cal yr BP. The deposition rate is approximately 0.20 cm/yr.

21774	365.0 - 368.0	wood	7,359 ± 34	8,041 - 8,219	B	Phountong (2016)
21775	381.0 - 385.0	leaves, charcoal	7,460 ± 37	8,192 - 8,363	A	Phountong (2016)

4.4.2 Chronology of TLN-CP7

The chronology of TLN-CP7 based on four ^{14}C dates obtained on charcoal, leaves, and seed (Table 8). The dated plant remains to provide age from 7,593 – 7,759 cal yr BP to recent.

The dating of charcoal (samples no. 030464) was taken from unit C*, which is a lowermost of the core, is about 7,593 – 7,759 cal yr BP.

Sample no. 030463 and 030462 were taken from unit D at 430.0 and 250.0 cm depth below water surface, respectively. The dating results of sample no. 030463 are about 7,510 – 7,543 cal yr BP. Whereas sample no. 030462, which is an upper layer, is about 7,582 – 7,694 cal yr BP (Table 8). These dating results suggest that the sediment was possibly disturbed by organisms or bioturbating activities e.g. borrowing (Gingras et al., 2015). Alternatively, the occurrence of contamination during dating sample preparation. Nevertheless, the dating results of both samples have a similar range of possibilities (Table 8).

Fortunately, there are the dating results of TLN-CP5 (Phountong, 2016), which can be used to correlate with TLN-CP7 (Fig. 34). The dating result of the top of unit C* in TLN-CP7 and the bottom of unit D in TLN-CP5 are about 7,593 – 7,7590 and 7,582 – 7,694 cal yr BP, which are considered to resemble (Fig. 36). In addition to the lithology of the sediment sequence is reliable evidence that supports the sediment in unit D from both cores beginning to deposition at the same time. According to the dating results, it is possible that unit D of both cores deposits with a similar rate is about 1.50 cm/yr in the initial period. And the thickness of grey clay, which deposited after 7,510 – 7,543 cal yr BP, shows a rapid deposition rate of unit D in TLN-CP7. Unfortunately, we do not collect any plant remains for dating between 250.0 and 175.0 cm depth below water surface, therefore, we cannot specify the time of changing sediment characteristics from unit D to unit E.

The dating of plant remains in sample no. 030461 was taken from the lower part of unit E that suggest the modern age (Table 8).

Table 8 ^{14}C dated for TLN-CP7.

Lab ID	Depth below water surface (cm)	Measured material	^{14}C date age (BP $\pm 1 \sigma$)	Calibrated age (2σ) (cal yr BP)	Units	Published in

CHAPTER V

DISCUSSION

The plants growing around the lake are the major source of organic matter in the sediments (Meyers and Ishiwatari, 1993; Pu et al., 2017). And the vegetation dynamics are important records to assess changes in the environment (Pu et al., 2017; Wang et al., 2017). Consequently, the organic remains to produce by the surrounding plants (pollens and chemical molecules, etc.) can be used for environmental reconstruction.

The plants can be generally classified by their morphology, anatomy, and chemotaxonomy. The chemotaxonomy is a new approach for the classification that is based on the plant chemical constituents producing from their biosynthetic pathways. These chemical constituents are often specific and limited to relate taxonomical organisms (Singh, 2016).

Aliphatic hydrocarbons, especially the *n*-alkanes, are widely used for plant classification (Bush and McInerney, 2013; Ficken et al., 2000) and paleoenvironmental reconstruction (Guo et al., 2014). The *n*-alkanes are the straight-chain hydrocarbons, which are stable and highly resistant molecules, because of their single bond and lack of functional groups. Consequently, the *n*-alkanes can survive in the fossil records for a long time (Eglinton and Hamilton, 1967; Eglinton and Eglinton, 2008). Each plant group generally produced their specific *n*-alkanes patterns (Meyers and Ishiwatari, 1993). Furthermore, the *n*-alkanes can be found in both modern and fossil plants (Bush and McInerney, 2013; Dubois et al., 2014; Ficken et al., 2000), soils and paleosols (Kuhn et al., 2010), and also sediments (Meyers, 2003; Pu et al., 2017; Zhang et al., 2017). Consequently, the *n*-alkanes are widely used to classify source of organic matter and to reconstruct the past environment.

The discussion in this chapter can be divided into three parts, i.e. the *n*-alkanes in modern plant samples and sediments, and the environmental reconstruction in Thale Noi.

5.1 Modern leaf plant

5.1.1 Distributions of *n*-alkane in modern leaf plants

For the modern plant samples, the *n*-alkanes distributions in true mangrove plants are diverse patterns including the long-, and short-chain predominance, and the bimodal distribution. The *n*-alkane distribution in *Avicennia marina*, *Rhizophora apiculata*, *Rhizophora mucronate* (KSC) and *Sonneratia caseolaris* are the long-chain predominance that agrees well with those of the previous study by Hogg (1984) (Fig 37). Meanwhile, *Barringtonia asiatica* (TLN), *Bruguiera gymnorhiza*, *Rhizophora mucronate* (KKB) and *Sesuvium portulacastrum* are dominated by the short-chain *n*-alkanes. *Barringtonia asiatica* (KKB) however shows the bimodal pattern in the *n*-alkanes distribution.

The *n*-alkanes distributions in back mangrove plants can be divided into the long-chain predominance in *Acrostichum aureum*, and short-chain predominance in *Oncosperma tigllarium* and *Xylocarpus granatum*. Despite Poaceae (*Bambusoideae*) and *Casuarina equisetifolia* can be classified to the mangrove associate plants, their *n*-alkane distributions are different. The long-chain *n*-alkane predominance prevails in Poaceae (*Bambusoideae*), which corresponds well with the previous studies (Bush and McInerney, 2013, 2015; Pu et al., 2017; Rommerskirchen et al., 2006). However, *Casuarina equisetifolia* from KKB is dominated by the short-chain *n*-alkanes, while the sample of the same plant from TLN shows the bimodal distribution.

The analysis of *n*-alkanes distributions in this study leaves two interesting points. Firstly, although the epicuticular wax has been generally considered to produce the long-chain *n*-alkanes, especially from C₂₁ to C₃₇, many plant samples are here dominated by the short-chain *n*-alkanes (Herbin and Robins, 1969; Kolattukudy, 1970; Kuhn et al., 2010; Rao et al., 2011). Secondly, the discrepancies of the *n*-alkanes distribution of the same taxon from the different sites have been found in *Sonneratia caseolaris*, *Rhizophora mucronate*, *Barringtonia asiatica* and *Casuarina equisetifolia* (Fig 37). This inconsistency can possibly be explained by that not only genetic but also external factors play an important role in the *n*-alkane distribution in the plants (Jia et al., 2015; Liu and Liu, 2016).

The assumption of the environmental control is supported by the similarity of the *n*-alkanes distribution in different plant group that was taken from the same sites.

Most of samples collected from KSC, which is the intertidal zone, for example, demonstrate the *n*-alkane distribution of the long-chain predominance (Fig. 38). The *n*-alkanes distributions in *Rhizophora mucronate*, *Rhizophora apiculate*, *Avicenia marina* and *Sonneratia caseolaris* consist well with those in Hogg et al. (1988) (Fig. 41). The exception is *Sesuvium portulacastrum*, which is dominated by the short-chain *n*-alkanes for this site (Fig. 38).

Figure 37 The distributions of n-alkane in same plant species from distinctive sits. The distinctive colored bars represents the plants which collected from distinctive sits; blue bar = Kung Krabaen Bay (KKB), green bar = Khun Samut Chin Temple, and red bar = Thale Noi

Figure 38 Distributions of *n*-alkane in modern plants, which were collected from Khun Samut Chin Temple (KSC), Samut Prakan Province.

Figure 39 Distributions of *n*-alkane in modern plants, which were collected from Kung Krabaen Bay (KKB), Chantaburi Province.

Another example is the distributions of *n*-alkane in the modern plants taken from KKB, which is the field experiment for mangrove development. The *n*-alkanes distributions in most of the samples from this site are the short-chain predominance, which C₁₆ and C₁₇ are the most abundant (Fig. 39). The dominance of the short-chain *n*-alkanes in this experimental field can possibly be explained by the cultivation, such as fertilizers and pesticide (Pitty, 1988).

Figure 40 Distributions of *n*-alkane in modern plants, which were collected from Thale Noi (TLN), Phatthalung Province.

However, it is not in all cases that the similar *n*-alkanes distribution can be observed from the same site. The plants were taken from TLN, for example, demonstrate diverse pattern of the *n*-alkane distributions. The distributions of *n*-alkane in Poaceae (*Bambusoideae*) and *Sonneratia caseolaris* are the long-chain predominance that consists well with the previous studies (Bush and McInerney, 2013; Hogg et al., 1988; Rommerskirchen et al., 2006). Bush and McInerney (2013, 2015) suggest that it is difficult to separate grasses from the woody plants since the *n*-alkane are varied in the mangrove associate. Moreover, the *n*-alkanes distributions in *Barringtonia asiatica* and *Casuarina equisetifolia* are the long-chain predominance and the bimodal distribution, respectively.

The *n*-alkane distributions in the true mangrove plants taken from KSC, KKB, and TLN were further compared with those from Queensland (Hogg et al., 1984) (Fig. 41 to 43). The *n*-alkane distribution patterns in the modern plant from KSC and TLN

agree with Hogg et al (1984) (Fig 41, 42). In contrast, the pattern in the modern plants from KKB is significantly diverse from Hogg et al (1984) (Fig. 43).

These all together also support that the environmental conditions are also an important factor controlling the *n*-alkanes production in the plant epicuticular (Hogg et al., 1988). Despite many studies suggest that a basic genetic potentially controls the composition of the epicuticular wax formation, environmental factors can affect the chemical contents and the specific pattern in some situations (Baker, 1974; Guo et al., 2014; Herbin and Robins, 1969; Pitty, 1988). The environmental factors, e.g. photoperiods, temperature, humidity, and elevation, make a shift in the chain length of the *n*-alkanes. And each plant responds to the same environmental factors in a different way (Baker, 1974; Maffei et al., 1993; Pitty, 1988; Rao et al., 2011; Wang et al., 2018; Wilkinson, 1972, 1974).

Figure 41 Comparison of similar *n*-alkane distribution between mangrove plants from Khun Samut Chin Temple (KSC) and Hogg et al (1984), including *Rhizophora mucronate*, *Rhizophora apiculata*, *Avicenia marina*, and *Sonneratia caseolaris*.

Figure 42 Comparison of similar *n*-alkane distribution between *Sonneratia caseolaris* from Thale Noi (TLN) and (Hogg and Gillan, 1984).

Figure 43 Comparison of dissimilar *n*-alkane distribution between mangrove plants from Kung Krabaen Bay (KKB) and (Hogg and Gillan, 1984), including *Bruguiera gymnorhiza*, *Rhizophora mucronate*, and *Xylocarpus granatum*.

5.1.2 The average chain length (ACL) and carbon preference index (CPI) in the modern plants

Despite the ACL_T and CPI_T values are diverse in each plant group, these values possibly can be grouped by their locations (Fig. 44). The ACL_T values in the sample taken from KSC, KKB, and TLN are 28.39 ± 4.43 , 20.35 ± 1.87 , and 24.49 ± 4.45 . These results suggest that the long-chain predominance can be observed in the samples from KSC and TLN. However, the ACL_T in the plant samples taken from KKB suggests the predominance of the short-chain *n*-alkanes that consist well with the distribution of the *n*-alkanes in the previous section.

The CPI_T value is obviously different based on the plants sample location. The CPI_T are 5.55 ± 3.54 , 0.87 ± 0.09 and 1.80 ± 1.21 in the plant samples taken from KSC, KKB and TLN, respectively. The leaf waxes generally produce CPI value of higher than 1 or the odd over even predominance (OEP) carbon chain length (Bush and McInerney, 2013; Pu et al., 2017). The high CPI values of leaf wax can be explained by the plant physiology (Baker, 1974). The plants growing in the coastal environment, for example, are necessary to produce more leaf wax in order to reduce their transpiration (Rhee et al., 1998). The CPI in the plant samples taken from KSC and TLN suggest that they are the OEP carbon chain length.

However, the CPI value of less than 1 can be found in the samples from KKB. This even over odd predominance (EOP) carbon chain length in leaf waxes are generally explained by a bacteria and fungi contamination or an experimental error owing to the low concentration of *n*-alkanes samples (Herbin and Robins, 1969). During this experiment, the total lipid obtained from *Casuarina equisetifolia* and *Barringtonia asiatica* from KKB and TLN became sticky like gum which is difficult to elute. This is possibly caused by a low concentration of *n*-alkanes and the EOP carbon chain length in these samples. Alternatively, the even over odd predominance (EOP) of carbon chain length can be found in soils, sediments or mature source rocks caused by decomposition or alteration processes (Eglinton and Hamilton, 1967). Some studies suggest that the EOP has been attributed by the highly saline carbonate environments (Dembicki Jr et al., 1976), and anthropogenic fossil fuel pollution (Lichtfouse et al., 1997). Moreover, Kuhn et al. (2009) also report that the productions of the predominance of short-chain *n*-alkanes with EOP carbon chain length can be

observed in the higher plants growing on the biomass burning area. These all together point to another possibility of the growing conditions affected on the production of *n*-alkanes in plants.

Figure 44 demonstrates the scatter plot of ACL_T against CPI_T values based on the sample locations. The samples with low ACL_T values, which range from 18 to 24, are usually low CPI_T of approximately 1 and vice versa. For the modern plant samples taken from KSC, the ACL_T values are slight difference of about 30, while CPI_T values diverse from 1 to 12. However, the ACL_T value of *Sesuvium portulacastrum* from KSC is relatively low compare to those values from other plants. In contrast, the CPI_T values are almost the same of about 1, while ACL_T values are varied from 18 to 23. ACL_T and CPI_T can be divided into two groups, i.e. *Casuarina equisetifolia* and *Barringtonia asiatica*, and *Sonneratia caseolaris* and Poaceae (*Bambusoideae*). The CPI_T of lower than 1 can be found in the former plants group. However, the ACL_T of *Casuarina equisetifolia* and *Barringtonia asiatica* are slightly varied of about 21.6 and 19.8, respectively. These values of *Casuarina equisetifolia* and *Barringtonia asiatica* from TLN are comparable with those from KKB. The ACL_T of *Sonneratia caseolaris* and Poaceae (*Bambusoideae*) are almost the same of approximately 28 but CPI_T of these plants are 11.3 and 3.1.

Since the numbers of plant samples are small, the applicable statistic approach on this analysis is possibly not proper. It is a strong suggestion to collect more samples together with diverse plant species for the future study, Alternatively, the chemotaxonomy is necessary to be validated with the other biomarkers, i.e. fatty acids, aldehyde, ketone, alcohol, alkane, etc. It is because the proportion of wax components are distinctively different in each plant species, e.g. a low alkane concentration in sugar cane leaf wax and a high concentration of alkanes in the leaf wax of *Cotyledon orbicularis* (Eglinton and Hamilton, 1967). Fatty acids and fatty acid-derived compounds are major compositions in Geranium and Erodium, therefore, they were used as a marker in the intergeneric (Herbin and Robins, 1969; Hogg and Gillan, 1984; Vogts et al., 2009), etc. Despite the chemotaxonomy based on the *n*-alkanes distributions are possibly not work in all species (Vogts et al., 2009), the *n*-

alkanes have been appropriately applied for paleoenvironmental reconstruction owing to their high resistance (Bush and McInerney, 2013).

Figure 44 Scatter plots of ACL_T versus CPI_T of n -alkane in modern plants based on plant groups (left) and locations (right).

5.2 Sediment

5.2.1 Distributions of n -alkane in sediment

The long-chain n -alkanes (C_{21} to C_{35}) in epicuticular waxes of leaves are generally produced by higher plants and highly resistant to microbial degradation after deposition. Consequently, the n -alkanes ranging from C_{21} to C_{35} in sediments from Thale Noi were here focused. The n -alkanes in the modern plants were subsequently compared with those in the sediment successions TLN-CP5 and TLN-CP7 in order to assess the environmental history in Thale Noi.

The n -alkane distributions in the sediment from core TLN-CP5

The sediment core TLN-CP5 was taken from the western sub-basin of Thale Noi. Yoojam (2015) constructed the lithostratigraphy of this core. The grain-sized distribution and loss on ignition were further analyzed by Phountong (2016), and

pollen analysis was studied by Nudnara (2016). These results are discussed together with the *n*-alkanes analysis in this section.

C₂₈ is the most abundant *n*-alkanes in the lowermost layer of core TLN-CP5, which is a stiff light grey clay of unit A (Fig. 21). A high concentration of C₂₈ is possibly derived from non-photosynthetic bacteria (Tanner et al., 2007; Tanner et al., 2010) in a deep water environment. This unit is a barren zone of pollen (Nudnara, 2016). But it is partly similar with the intertidal sediments based on Chaimanee et al. (1985). These all together suggest that Thale Noi was under flooding.

The most abundant *n*-alkanes in unit B are C₂₅, C₂₉ and C₃₁ (at 360, 350 and 340 cm depth below water surface, respectively). The predominance of the long-chained *n*-alkanes suggests that their provenances are from higher plants (Ficken et al., 2000; Pu et al., 2017; Ratnayake et al., 2017). According to the loss on ignition, the dark grey clay of unit B consists of slightly higher organic matter content than those in unit A (Phountong, 2016).

However, the sediment sample at 360 cm depth below water surface is dominance of C₂₅, which was not found its dominant in the modern plant samples. This depth is also a barren zone of pollen (Nudnara, 2016). These all together possibly suggest that C₂₅ is originated from other plants that do not include in this study. Since the high runoff can be reconstructed based on grain size analysis, the organic matter with dominated C₂₅ was transported to the site (Phountong, 2016).

The most abundant *n*-alkane in the sample at 350 cm depth below water surface is C₂₉, which is resembled with *Rhizophora mucronate* from KSC (Fig. 22). However, *Brugueira*, *Rhizophora*, *Stenochlaena*, and *Acrostichum* have been found in pollen analysis at this depth (Nudnara, 2016). *Brugueira*, *Rhizophora* and *Stenochlaena* are the true mangrove plants. Their concentration is much higher than that of *Acrostichum*, which is the back mangrove plant. Consequently, the mangrove plants are a possibly major source of C₂₉.

C₃₁ is the most abundant in a sample at 340 cm depth below water surface. This *n*-alkane is the main peak in *Brugueira* and *Rhizophora apiculate*, which are the mangrove plants. However, the most abundance pollen at this depth is *Acrostichum*, which is about 80%. Despite the main peak of *Acrostichum* is C₃₃, C₃₁ has been found in a high concentration. Therefore, C₃₁ is here supposed to be produced by both the

mangrove and back mangrove plants. The dominant of C₃₁ possibly indicate shrinkage of mangrove forest and expansion of back mangrove comparing to the preceding sample at 350 cm depth below water surface.

C₃₁ is also predominance in the samples at 330, 320 and 310 cm depth below water surface of unit C, and at 290, 280 and 270 cm depth below water surface of unit D-1 reflecting a presence of both mangrove and back mangrove plants. Pollen records also suggest the dominance of back mangrove plants from 340 to 330 cm depth below water surface and mangrove plants from 310 to 270 cm depth below water surface (Nudnara, 2016).

The sample at 300 cm depth below water surface is near a boundary between unit C and D at about 298.5 cm depth below water surface, which expected to be a hiatus by Phountong (2016). Despite *Rhizophora* is the highest pollen concentration in this sample, the most abundant n-alkane is C₂₇, which C₂₇ is not significantly recognized in the modern plant analysis (Nudnara, 2016). Since C₂₇ has generally considered being produced by the terrestrial plant, this alkane is possibly coming from the vegetation that is not including in this study (Bush and McInerney, 2013; Meyers, 1997).

The concentration of C₂₁, which is mainly originated from aquatic plants, is remarkably high in the samples from 260 to 240 cm depth below water surface (unit D-2) (Ficken et al., 2000). However, C₂₁ has been found in the very low concentration in all the modern plant samples. This depth has been considered to be an abundance of mangrove plants in regarding to the pollen analysis (Nudnara, 2016). The limited number of data in this study cannot explain these discrepancies between n-alkanes and pollen analysis. However, the prevailing C₂₁ was here hypothesized that it was transported from the wetland further in the coastal zone.

The n-alkane distribution in the sediment at 230 cm depth below water surface is dominated by C₂₆, which is the even carbon number and inconsistent with the modern plant sample analysis. The predominance of the even carbon number in n-alkanes is possibly caused by either decomposition of the organic matter due to microbial activities (Reddy et al., 2000). However, pollen records indicate a dominant of mangrove forest and a stillstand of sea level at this depth (Nudnara et al., 2016).

The further investigations for the even carbon number *n*-alkanes, therefore, are necessitated.

C₃₁ become again predominance from 220 to 190 cm depth below water surface that agrees well with the abundance of *Rhizophora* in the pollen analysis (Nudnara, 2016). The C₂₇ was replaced from 190 to 155 cm depth below water surface indicating woody or tree abundance. The sediments of the middle to the uppermost of unit E have C₂₇ predominance, indicating woody or tree abundance. This result compares well with the occupation of Poaceae in the pollen stratigraphy (Nudnara, 2016), and increase in runoff into the lake (Phountong, 2016).

Figure 45 Distributions of *n*-alkane in sediment from TLN-CP5 along with age depth. Lithostratigraphy reported by Yoojam (2015). And age depth reported by Phountong (2016).

The n-alkane distributions in the sediment from core TLN-CP7

TLN-CP7 is a sediment core, which was taken from the eastern part of Thale Noi. This core consists of three sediment units, i.e. unit C*, D and E from bottom to top. The lithostratigraphy for this core was constructed by Yoojam (2015).

The compacted peat of unit C* at 437 cm depth below water surface is dominated by C₂₉, which is generally produced by the terrestrial plants (Meyers and Ishiwatari, 1993). However, the modern plant samples together with the interpretation with pollen analysis in core TLN-CP5 suggest that C₂₉ is the dominant peak in *Rhizophora mucronate* and/or mainly produced by the mangrove plants. This sediment layer is therefore presumed to deposit under the intertidal environment. The C₂₁ is the most abundant in the sediment unit D from 433 to 320 cm depth below water surface. According to the interpretation in core TLN-CP5, the C₂₁ is mainly produced by the higher plant and transports to the lake. Consequently, the dominance of C₂₁ indicates an increase in runoff to the lake. This high runoff period was possibly interrupted by an environmental shift between 410 and 380 cm depth below water surface in regarding to the predominance of the even carbon number of C₂₆ and C₂₄. The abundance of the even carbon number in *n*-alkanes (C₁₂ - C₂₆) is present in lacustrine sediments and coastal soils (Ekpo et al., 2005). However, C₂₄ was possibly derived from *Xylocarpus granatum*, which their pollens were found in the lowermost of unit D from TLN-CP5. However, the limited information here does not allow us to specify the source of these even number *n*-alkanes.

The environment fluctuations can be observed between 300 and 160 cm depth below water surface, since the carbon numbers in the *n*-alkanes are varied from C₂₄ to C₂₉. The even carbon number of C₂₆ and C₂₄ are again dominance at 300, 260 and 200 cm depth below water surface, and 190 cm depth below water surface, respectively. The abundance of C₂₆ suggests microorganism presence. The predominance of these even carbon numbers in sediments has been attributed to special sources found under different conditions or its microbial alteration (Wang et al., 2010). The odd carbon number of C₂₇ and C₂₉ are abundance at 240, 170 and 160 cm depth below water surface, and 280, 220, and 180 cm depth below water surface. The C₂₇ and C₂₉ are mainly produced by terrestrial plants. According to the *n*-alkane in modern plants and

the interpretation in core TLN-CP5, C_{29} is here possibly obtained from *Rhizophora* and indicate the intertidal environment. However, C_{27} in the samples from 170 to 160 cm depth below water surface is more likely to be originated from the terrestrial plants since it can be correlated well with those in core TLN-CP5. Alternatively, the *n*-alkane distribution at 160 cm depth below water surface shows the odd carbon number predominance (C_{23} , C_{25} , C_{27} C_{29}) which also possibly reflects the combination of organic matter inputs (Pearson et al., 2007).

Figure 46 Distributions of *n*-alkane in sediment from TLN-CP7 along with age depth. Lithostratigraphy reported by Yoojam (2015).

Figure 47 Correlation of distribution of C₂₁, C₂₉, and C₃₁ chain length in sediments between TLN-CP5 and TLN-CP7 based on sedimentary unit.

5.2.2 The average chain length (ACL), carbon preference index (CPI), and proportion of aquatic plants (P_{aq}) in sediment

In general, the average chain length (ACL) values can be used to indicate types of vegetation and organism (Andersson et al., 2011; Pu et al., 2017). The recent studies including our modern plant samples suggest that the ACL is not the good biomarkers for chemotaxonomy because this parameter is possibly affected by growing environment (Maffei et al., 1993; Rao et al., 2011). In the current study, ACL_{21-35} in sediments were calculated to compare with those in the modern plants in order to examine the origin of organic matters in Thale Noi (Bush and McInerney, 2013; Pu et al., 2017).

However, the ACL_{21-35} ranges in the cores TLN-CP5 and TLN-CP7 are similar with those values from the modern plants. This result suggests that the plants surrounding the lake are the major sources of the organic matter (Meyers, 1997; Pu et al., 2017). Nevertheless, the classification of plant group based on only the ACL_{21-35} is very difficult. The ACL_{21-35} in *Sesuvium portulacastrum* and *Casuarina equisetifolia*, which is a true mangrove and mangrove associate plants, for example, are approximately 26. Meyers and Ishiwatari (1993), and Ficken et al. (2000) suggest that ACL_{21-35} values of lower than 20, from 21 to 25, and higher than 27 correspond to microorganisms, aquatic plants, and land plants, respectively.

The ACL_{21-35} in TLN-CP5 are gradually increased from the bottom of unit A to the top of unit C. Then they gradually decrease to the middle of unit D and subsequently, the values rise from the middle of unit D to unit E. The uppermost of unit E have a lower value than the previous layer.

The ACL_{21-35} values in the TLN-CP7 are similar to the ACL_{21-35} in unit D of TLN-CP5. The ACL_{21-35} are gradually fallen from the lowermost of unit C* to the middle of unit D and subsequently increase from the middle to the uppermost of unit D. Then they decrease again in unit E.

In sediments, CPI is used to indicate the diagenesis of straight-chain lipid hydrocarbon by microbial organism (Meyers and Ishiwatari, 1993). The CPI value of higher than 1.5, about 1, and less than 1 correspond to plant wax, marine microorganisms, and petroleum residue contaminations, respectively (Kennicutt et al., 1987).

The CPI_{21-35} values from sediment samples are relatively low compared to those in the modern plants. This can be explained by the complicate decomposition pathways in the sediment (Meyers, 1997). However, the corresponding of CPI_{21-35} is ACL_{21-35} suggest that the CPI_{21-35} is possibly response to the environmental changes. The sediment in TLN-CP5 shows a fluctuation of CPI_{21-35} in sediment unit A to C. The exception is at 310 cm depth below water surface that CPI_{21-35} increase and reach its maximum of 3.2 that suggest a rapid accumulation rate or a low decomposition rate of organic matter. This parameter becomes a similar pattern to the ACL_{21-35} variation in the sediment unit D and E.

The proportion of aquatic plant component (P_{aq}) is a biomarker parameter, which is used to distinguish land plant from aquatic plants in freshwater lakes (Andersson et al., 2011). According to Ficken et al. (2000), the P_{aq} value of less than 0.1 indicates the terrestrial plants. The P_{aq} value from 0.1 to 0.4 corresponds to the emergent plants, wetland plants or long-shore plants. And P_{aq} value from 0.4 to 1 represent the submerge/floating macrophytes (Ficken et al., 2000). In addition, this mediate P_{aq} value possibly corresponds to a mixed supply from terrestrial, emergent and submerged/floating plants (Ficken et al., 2000). Furthermore, some studies, P_{aq} value has been used to reconstruct the past water levels in peat bogs (Zheng et al., 2007). The predominance of emergent and submerged/floating plants can be used to consider water level of the lake, emergent plants grow well in the shallow lake because emergent plants are rooted in the lake bottom. Therefore, the shallow lake is possibly dominated by both emergent and floating plants, whereas, the deep lake could be dominated by floating plants.

The P_{aq} is always opposing to the ACL_{21-35} and CPI_{21-35} . The P_{aq} in most of the sediments from TLN-CP5 is about 0.1 to 0.4, representing mixed input from diverse plant groups. However, a low P_{aq} of about 0.1 can be found in the sample from 290 to 340 cm depth below water surface that relate to land plants. The dominant terrestrial plants correspond with the results from the *n*-alkane distribution and ACL_{21-35} . Moreover, P_{aq} reached its maximum value of 0.67 in the uppermost layer of TLN-CP7 suggest that the submerge or floating plants are abundance corresponding to the recent conditions of Thale Noi, which is a freshwater swamp.

Figure 48 Correlation of ACL_{21-35} , CPI_{21-35} , and P_{aq} in sediment between TLN-CP5 and TLN-CP7. Lithostratigraphy reported by Yoojam (2015). And age depth of TLN-CP5 reported by Phountong (2016).

Modified after Nudnara, 2016

5.3 Environmental reconstruction in Thale Noi

The results of *n*-alkane biomarker analysis along with ^{14}C AMS dating of TLN-CP5 (Phountong, 2016), it shows the environmental change in Thale Noi during the Holocene. Before 8,300 cal yr BP, C_{28} is the most abundant in the sediment that possibly derived from non-photosynthetic bacteria (Tanner et al., 2010), suggesting a deepwater environment, in accord with pollen disappearance (Nudnara, 2016). Consequently, we speculate that is possible the whole area was covered by a high sea level (Nudnara, 2016; Phountong, 2016). Otherwise, several studies reported the transgression in the Gulf of Thailand at about 8,500 yr BP (Chaimanee et al., 1986; Horton et al., 2005).

After 8,300 cal yr BP, the ACL_{21-35} , and CPI_{21-35} values increased gradually, while P_{aq} values decreased until about 8,100 cal yr BP, suggesting that the sea level gradually decline which relate to the presence of back mangrove (Nudnara, 2016). But Horton et al (2005) reported that during about 8,420 – 8,190 cal yr BP, true mangrove pollen predominance, representing the sea level transgression.

About 8,100 – 8,000 cal yr BP, sediments in TLN-CP5 are dominated by C_{27} , C_{29} , and C_{31} that is the representative of a woody plant. That corresponding to the high concentration of true mangrove pollen taxa (Nudnara, 2016). A hiatus presents at 298 cm depth below water surface in the TLN-CP5, it approximately extended from 8,000 – 7,600 for 400 years (Phountong, 2016). Subsequently, a transgression had begun at about 7,600 – 7,500 cal yr BP based on the *n*-alkane distribution (Fig. 45), and their parameters (Fig. 48). In addition to *Rhizophora* and *Bruguiera* pollens were vast dominant in western sub-basin (Nudnara, 2016). On the other hand, Horton et al (2005) reported that regression had begun at about 7,880 – 7,680 cal yr BP.

Freshwater more supplied into the lake meanwhile effect of sea level was decline, according to the change from C_{31} to C_{21} are consistent with the decreased ACL_{21-35} while P_{aq} is increased. They suggest that aquatic macrophytes are widely predominant during 7,500 – 7,200 cal yr BP. About 7,200 cal yr BP, C_{21} turn to C_{31} again that represent freshwater supply was gradually declining to correspond to the increased ACL_{21-35} and decreased P_{aq} . Accordingly, the concentration of freshwater pollens can support the regression of sea level (Nudnara, 2016).

The shift from C_{31} to C_{27} , the increased ACL_{21-35} and the highest CPI_{21-35} refer to the continental environment. Likewise, constantly P_{aq} which indicate a mixture of aquatic and mangrove associate after 7,200 cal yr BP to recent. These suggest freshwater swamp in the recent.

CHAPTER VI CONCLUSION

6.1 Conclusions

This study has analyzed the *n*-alkane distributions and generality of *n*-alkane parameters in the leaf waxes of 16 recent plant samples (12 species) from Kung Krabaen Bay Royal Development Study Center (KKB), Chantaburi Province, Khun Samut Chin Temple (KSC), Samut Prakan Province, and Thale Noi (TLN), Phatthalung Province. All these plant samples are mangrove forest which reflects the sea level fluctuation and environmental change. The mangrove plants were separated into true mangrove, back mangrove, and mangrove associate based on mangrove zonation (Kamaludin et al., 1988). We expected plants in each group to create a similar *n*-alkane and the characteristic of *n*-alkane in each group will be a biomarker for the chemotaxonomy. And the *n*-alkane can be applied in reconstructing the paleoenvironment. As the results we, therefore, concluded as follows: (Pitty, 1988)

- Despite the *n*-alkanes distribution and their parameters in the modern plant leaves are generally similar in the same species, the shift in the *n*-alkane distributions can be found in some species. These discrepancies can possibly explained by the influence of their local environments.
- The species of modern plant samples in this study are quite multitudinous, there are diverse species. The only *n*-alkane is not a potential biomarker for every plant species. Consequently, the *n*-alkane distribution, average chain length (ACL), and carbon preference index (CPI) cannot be used to classify the modern plant into the groups of mangrove zonation.
- The database of *n*-alkanes distribution derived from mangrove forest around the gulf of Thailand has been report in detail in the Appendix B.

And further analyzed the *n*-alkane distributions and generality of *n*-alkane parameters in 22 and 18 sediment samples from TLN-CP5 and TLN-CP7, respectively at Thale Noi and compared them with *n*-alkane of modern plants in order

to identify vegetation types of organic matters in the lake. Conclusion, our findings and their significance here:

- First, the results illustrate that the *n*-alkanes in the lake sediments of Thale Noi derive from mixture sources and they reflect environmental changes.
- Second, the major sources of organic matter are derived from surrounding plants, but the *n*-alkane in sediments cannot be used to accurately interpret as expected plant species (true mangrove, back mangrove, and mangrove associate) because of their biochemical processes. However, they can be used to classify as vegetation types (aquatic plant or terrestrial) which leading to sea level or water inpretation.
- The last one ACL, CPI and P_{aq} values that are a good proxy, reflecting the organic matter types.

This study demonstrates that relationship of the *n*-alkanes distributions between modern plants and lake sediments is complicated. Because *n*-alkanes of lake sediment are the mixture sources, not only plant and their geo-biochemical processes. In addition to growing environment of modern plant and fossil plants are different. Consequently, *n*-alkane of both cannot use to compare each other. However, the advantage of using *n*-alkane and their parameters is that they can provide comprehensive information for the environmental reconstruction.

6.2 Suggestion and recommendation

Since the proportion of components in the wax is different in each plant species, therefore, more than one compound should be used for chemotaxonomy. And should limit the family of plant samples in order to not allowing each group to have a variety of plant. Alternatively, the number of plant samples in the same species should be increased to ensure that the *n*-alkane distribution has been represented by those plants.
