5070350521: MAJOR CHEMICAL ENGINEERING

KEYWORDS: TITANIUM DIOXIDE / THIN FILM / HYDROPHILICITY / METAL LOADING

PIYAPHONG PHROMSALEE: EFFECT OF METAL LOADING ON PHOTO-INDUCED HYDROPHILICITY OF TITANIUM DIOXIDE THIN FILMS.
ADVISOR: AKAWAT SIRISUK, Ph.D., 106 pp.

Titanium dioxide sol (TiO_2) was synthesized using a sol-gel method. Various amount of silver, tungsten, copper, or molybdenum precursor solution were added to TiO_2 sol to produce Ag-, W-, Cu-, or Mo- TiO_2 sol. Then the modified TiO_2 sol was coated on glass plates using a dip-coating technique to form the thin films. The as-prepared films were calcined at $350\text{ }^\circ\text{C}$ for two hours. The hydrophilicity of the thin films was evaluated by measuring the contact angle of water droplet on the film surface under UV irradiation. Addition of silver or tungsten to TiO_2 enhanced hydrophilicities of the mixed oxide films. TiO_2 film containing 3.0-5.0 mol% silver or 1.0-1.5 mol% tungsten not only possessed the best hydrophilic properties but also improved their abilities to retain hydrophilicity after removal of UV irradiation. This was attributed to silver and tungsten inhibiting the recombination of photo-generated electrons and holes, which agreed with the results from photoluminescence spectra. Addition of copper (0.1-5.0 mol%) or molybdenum (0.1-1.0 mol%) to TiO_2 did not improve the hydrophilicity of the thin films because the photo-generated electrons were captured by metal oxide instead of creating surface oxygen vacancies on TiO_2 surface. Furthermore, neither CuO nor MoO_3 possessed hydrophilicity. An increase in the content of copper or molybdenum in TiO_2 worsened the hydrophilic property of the thin film.

ACKNOWLEDGEMENTS

This dissertation would not have been possible to complete without the support of the following individuals. Firstly, I would like to express my greatest gratitude to my advisor, Dr. Akawat Sirisuk, for his invaluable guidance during the course of this work. Special thanks to Professor Piyasarn Praserttham, as the chairman, Dr. Apinan Soottitantawat and Dr. Soipatta soisuwan, members of the thesis committee for their kind cooperation.

The financial supports from Commission on Higher Education, the Thailand Reserch Fund (TRF), and Graduate School of Chulalongkorn University are also gratefully acknowledged.

Many thanks for kind suggestions and useful help to many friends at Center of Excellence on Catalysis and Catalytic Reaction Engineering who always provide the encouragement and assistance along the thesis study.

Finally, I also would like to dedicate this thesis to my parents who have always been the source of my support and encouragement.

CHAPTER I

INTRODUCTION

Titanium dioxide (TiO₂) is widely used in many applications such as photocatalyst for environmental purification, solar cells, pigment, UV absorber, gas sensor, catalyst support, self-cleaning, and anti-fogging surface, etc. As for TiO₂ thin films, there are actually two distinct photo-induced phenomena; the first one is the well-known photocatalytic process, which leads to the decomposition of organic pollutants in water and air to CO₂, H₂O, and other small organic compounds; the second one is the hydrophilic property, which occurs after TiO₂ surface is irradiated with UV light (Fujishima et al, 2000). Hydrophilic property of TiO₂ surface allows water to spread completely across the surface rather than remaining as droplets, which can be developed into self-cleaning and anti-fogging glasses and surfaces (Guan, 2005 and Yu et al., 2006). However, this property is not stable. The hydrophilic surface can return to hydrophobic state when being kept away from UV illumination for extended period of time.

The main problems of utilizing TiO₂ as a photocatalyst in photocatalytic process are the fast recombination rate of photo-generated electron-hole pairs, which lead to low photocatalytic activity, and the restriction of light absorption capability in visible region (Xin et al., 2007). In order to slow down the recombination rate and enhance the interfacial charge transfer efficiency, doping of transition metal ion into TiO₂ has been widely investigated. The transition metal including Fe³⁺ (Sonawane et al., 2005 and Xin et al. 2007), Ni²⁺ (Sharma et al., 2006), Co²⁺ (Iwasaki et al., 2000 and Bellardita et al., 2007), W⁶⁺ (Li et al., 2001; Bellardita et al., 2007 and Ke et al., 2008), Cu²⁺ (Li et al., 2004; Xin et al., 2008, and Xu et al., 2008), and Ag⁺ (He et al., 2002 and Xin et al., 2005) have been proven to act as traps for photogenerated electron-hole pairs, thereby prolonging the lifetime of electrons and holes and improving photocatalytic activity of TiO₂ (Sharma et al., 2006). Nevertheless, only few researchers have reported the effect of metal doping on hydrophilicity although

there may be a close correlation between photocatalytic activity and hydrophilic property of TiO_2 (Guan, 2005).

Therefore, in this study various metals (i.e., Ag, W, Cu, and Mo) were added to TiO_2 . The effects of metal loading on the hydrophilicity of thin films and their abilities to retain hydrophilic property after removal of UV irradiation were investigated. TiO_2 and metal-loaded TiO_2 sol were prepared by a sol-gel method and then were coated on glass plates using a dip-coating technique.

This thesis is arranged as follows:

Chapter II explains the basic information about TiO_2 , principles and applications of photo-induced hydrophilic property and presents the literature reviews of previous works related to this research.

Chapter III describes the synthesis of TiO_2 and metal loaded- TiO_2 using a sol-gel process, preparation of the thin films by a dip-coating technique and characterization of the thin films.

Chapter IV presents experimental results and discussion.

Chapter V presents overall conclusions of this research and recommendations for future research.

CHAPTER II

BACKGROUND INFORMATION

2.1 Information on titanium dioxide

TiO₂ is an n-type semiconductor, which is widely used in many applications owing to its exceptional optical and electronic properties, strong oxidizing power, chemical stability, non-toxicity, good mechanical strength and inexpensive (Litter, 1999). TiO₂ exists in three crystallographic forms of anatase, rutile, and brookite (see Figure 2.1); anatase (tetragonal), generally processes a higher hydrophilicity and photocatalytic activity than the other types of TiO₂; rutile (tetragonal), mostly common in nature and tends to be more stable at higher temperatures, which has higher opacity, greater density and inertness than that anatase. Moreover, it is used as a convertible pigment in paints and dyes industry. (Jiang and Chen, 2004); and brookite (orthorhombic), is a metastable phase, which is scarce and usually found only in minerals (Ohara et al., 2008). Moreover, it is difficult to prepare pure phase under laboratory condition.

Figure 2.1 Crystal structures of titanium dioxide: (a) anatase (b) rutile and (c) brookite. (<http://ruby.colorado.edu/~smyth/min/tio2.html>)

2.2 Synthesis of titanium dioxide by a sol-gel method (Su et al., 2004)

The sol-gel process occurs in liquid solution of organometallic precursors such as titanium isopropoxide, tetraethyl orthosilicate and zirconium propoxide. The precursor undergoes hydrolysis and condensation reactions, and form sol according to Equations 2.1 to 2.3.

where M and R are metal atom and typically an alkyl group, respectively. The sol is made of solid particles of a diameter of few hundred nanometers suspending in a liquid phase. After that, the particles condense into gel, in which solid macromolecules are immersed in a liquid phase. Drying the gel at low temperature (25-100 °C) produces porous solid matrices or xerogels. To obtain a final product, the gel is heated. This heat treatment serves several purposes, i.e., to remove solvent, to decompose anions such as alkoxides or carbonates to give oxides, to rearrange of the structure of the solid, and to allow crystallization to occur.

Using the sol-gel method, one can easily control a stoichiometry of solid solution and a homogeneous distribution of nanoparticles and metal oxides. In addition, the metal oxides can be prepared easily at room temperature and high purity can be obtained.

2.3 Photo-induced hydrophilicity of titanium dioxide thin film

The primary process involving photocatalytic process occurs upon irradiation of a semiconductor. A semiconductor is characterized by an electronic structure, in which a valance band (vb) and a conduction band (cb) are separated by a band gap (E_g). The band gap defines the wavelength sensitivity of the semiconductor to

irradiation. A photon with energy higher than or equal to the band gap energy is absorbed by a semiconductor particle. Then an electron (e^-) from the valance band is promoted to the conduction band with simultaneous generation of an electronic vacancy or hole (h^+) in the valance band. This process is photoexcitation of electrons. Figure 2.2 shows the photocatalytic process occurring on an irradiated semiconductor particle. In metal, two types of charge carriers, electrons and holes, immediately recombine on the surface or the bulk of particle in a few nanoseconds and the accompanying energy is dissipated as heat. In a semiconductor such as TiO_2 , however, the charge carriers survive for a longer period of time to allow themselves to be trapped in surface states where they can react with electron donor (D) or acceptor (A) species, which adsorbed on or closed to the surface of the particle (see Equations 2.4 to 2.7) (Litter, 1999). Subsequently, oxidation and reduction can be initiated.

Figure 2.2 Photocatalytic process occurring on an illuminated semiconductor particle (Litter, 1999).

The hydrophilicity of TiO₂ film was actually discovered by accident work that was being carried out at laboratory of TOTO Inc. in 1995. It was found that, if TiO₂ thin film was prepared with certain percentage of SiO₂, it acquired superhydrophilic property with water contact angle of ~0° after UV irradiation. Photo-induced hydrophilicity is different process from the photocatalytic decomposition of organic contaminants. Many researches have been reported such as, strontium titanate (SrTiO₃), which has almost the same photocatalytic activity as to TiO₂ but not become hydrophilic surface after UV irradiation (Miyachi et al., 2000) or WO₃, which shows photo-induced hydrophilicity but not exhibit photocatalytic activity (Miyachi et al., 2002). Furthermore the hydrophilic surface of TiO₂ after UV irradiation consists of large numbers of closely spaced domains with sizes of several tens of nanometers, which revealed by atomic force microscopic observation (Sakai et al., 2001). Generation of such a domain structure cannot be explained by removal and adsorption of carbon contamination is the only reason causing the surface wettability change on the TiO₂ surface.

Earlier, the present authors considered that this highly hydrophilic conversion originated from the clean surface produced by the decomposition of the contaminants on surface through conventional photocatalytic process. However, after a large number of experimental results which did not suggest the conversion of hydrophilic surface by photocatalytic decomposition was taking place such as, (1) hydrophilic conversion of TiO₂ and SrTiO₃ films after applying oleic acid on surface. Before and after applied oleic acid, both TiO₂ and SrTiO₃ films had the contact angle about 20° and 70° respectively. After UV irradiation, the water contact angle of SrTiO₃ film decreased and reached to initial contact angle about 20°, which surface adsorbed oleic acid was decomposed. But for TiO₂ film, the contact angle decreased to 0°, which was lower than initial contact angle (Miyayushi et al., 2000), (2) treatment of TiO₂ surface by warm concentrated NaOH solution, which strains were completely removed but it still showed hydrophilic conversion after UV irradiation (Sun et al., 2001), (3) sonication of hydrophilic surface of TiO₂ film in pure water back to the original less hydrophilic one. As the hydrophilic surface was sonicated in pure water, the surface strain were removed and highly hydrophilic was enhanced (saki et al., 1998),

and (4) on highly hydrophilic surface, it was found that the reconversion rate in a cleaner pure oxygen atmosphere is much higher than that in ambient condition. If carbon contamination is the only reason that gives rise to an increase of the water contact angle, then it might be reasonable to consider that the hydrophilic-to-hydrophobic conversion rate in an ambient condition should be higher than that in pure oxygen due to the relatively high concentration of carbon containing contaminants in the former condition. However, the result is the reverse (Sun et al., 2001). So the authors came to the conclusion that alternate mechanism for hydrophilic conversion exist other than the removal of organic contaminants on the surface (Irie and hashimoro, 2005).

The mechanism of photo-induced hydrophilicity is proposed on the basis of the reconstruction of the surface hydroxyl groups which occurs by adsorption of water molecules on the photo-generated defective sites of TiO₂ under UV light irradiation, and reach to highly hydrophilic surface. The formation of defective sites on TiO₂ surface can be expressed according to Equations 2.8 and 2.9 (Yu et al., 2002).

Figure 2.3 presents the mechanism of photo-induced hydrophilivity in TiO₂. When the TiO₂ surface is excited by UV illumination, photo-generated electrons are trapped at the surface of Ti sites as Ti³⁺ and immediately oxidized by adsorbed molecular oxygen, while the holes diffuse to TiO₂ surface, being trapping at lattice oxygen atoms to form O⁻ and be further oxidized by a second hole to form a neutral O[•] radical. The trapping of holes weaken the binding energy between Ti atom and the lattice oxygen atoms. Then two oxygen radicals are coupling and release as O₂ molecules, so the oxygen vacancies are created. Subsequently, water molecules can occupy these oxygen vacancies by dissociative adsorption to produce chemisorbed hydroxyl groups and then multiple layers of water molecules by Van der Waals forces and hydrogen bond (Fujishima et al., 2000; Lee et al., 2003 and Guan, 2005). The process gives rise to a hydrophilic surface. The longer the surface is illuminated with

UV light, the smaller the contact angle for water becomes and tendency to spread perfectly across the surface.

During long term storage in the dark place in air, the contact angle of water tends to increase up to certain saturated contact angle. This is ascribed to the gradual replacement of chemisorbed hydroxyl groups by oxygen from the air and the healing of surface defective sites, which return the surface geometric and electronic structures to the native TiO_2 surface (Wang et al., 1999). Consequently, the hydrophilicity is lost and the surface wettability changes from a hydrophilic state to hydrophobic state one. From the viewpoint of practicality and commercialization, it would be more valuable if the hydrophilicity of the TiO_2 films can remain for a long time, through the hydrophilicity could be fully recovered by illumination the TiO_2 surface again with UV light (Wang et al., 2000 and Yu et al., 2006).

Figure 2.3 Mechanism of photo-induced hydrophilicity of TiO_2 film. (\square denotes oxygen vacancy) (Sakai et al., 2001 and Saki et al., 2003)

2.4 Wettability and contact angle (De Gennes, 1985 and Irie et al., 2005)

Wettability is one of the most important on solid surface. The surface wettability is generally evaluated by the contact angle, which is the angle at which a liquid/vapor interface meets the solid surface. The contact angle is specific for any given system and is determined by the interactions across the three interfaces. Most often the concept is illustrated with a small liquid droplet resting on a flat horizontal solid surface (see Figure 2.4). Ideally, the droplet should be as small as possible because the force of gravity force, for example, can actually change the above-mentioned angle.

The theoretical description of contact angle arises from the consideration of a thermodynamic equilibrium between the three phases, namely, the liquid phase of the droplet (L), the solid phase of substrate (S), and the gas/vapor phase of the ambient (V). At equilibrium, the chemical potential in the three phases should be equal. It is convenient to frame the discussion in term of the interfacial energy or surface tension. The shape of the droplet is determined by the Young-Laplace Equation (see Equation 2.10) which, must be satisfied in equilibrium as follows in Equation 2.10.

$$\cos \theta = \frac{\sigma_{SV} - \sigma_{SL}}{\sigma_{LV}} \quad (2.10)$$

where θ is contact angle

σ_{SV} is surface tension between solid and vapor ambient atmosphere

σ_{SL} is surface tension between solid and liquid

σ_{LV} is surface tension between liquid and vapor ambient atmosphere

Figure 2.4 The force balance between the three surface tensions for determining the contact angle.

Young's equation is applicable only to an ideal surface, that is, homogeneous, rigid, insoluble and flat. However, real surfaces have surface roughness and surface heterogeneity. Wentzel modified Young's equation considering the surface roughness to obtain the Equation 2.11.

$$\cos \theta' = \gamma \cos \theta \quad (2.11)$$

where θ' is the apparent contact angle

γ is the surface roughness ratio between the actual surface area and the apparent surface area.

This equation indicates that the surface roughness enhances hydrophilicity of hydrophilic surface ($\theta < 90^\circ$) and also enhances the hydrophobicity of hydrophobic surface ($\theta > 90^\circ$).

The wettability of surface can be classified by the contact angle into four regions.

1. When $\theta < 5^\circ$, water can spread completely over substrate surface. This state is called "superhydrophilic".
2. When $5^\circ < \theta < 90^\circ$, the surface allows the substrate to be wetted and the water film is form on its surface. This state is called "hydrophilic".

3. When $90^\circ < \theta < 150^\circ$, the substrate has little or no tendency to adsorb water and tend to bead on the surface. This state is called “hydrophobic”.

4. When $\theta > 150^\circ$, water droplets simply rest on the surface, without actually wetting to any significant extent. This state is called “superhydrophobic”.

2.5 Relationship between photocatalysis and hydrophilicity (Guan et al., 2005)

In spite of the different mechanisms of photocatalysis and hydrophilicity, the correlation between the two effects is obvious. The photo-induced hydrophilicity of the film closely relates to the photocatalytic removal of organic substances from the film surface. When more hydroxyl groups can be adsorbed on the surface due to hydrophilicity, the photocatalytic activity is enhanced. Therefore, hydrophilicity can enhance photocatalysis. On the other hand, the film surface can adsorb contaminated compounds, which tend to turn the hydrophilic surface into hydrophobic surface. Nonetheless, photocatalysis can decompose the organic compound deposited on the surface into H_2O , CO_2 , and other small organic compounds to restore the hydrophilicity. As a result, photocatalysis can improve hydrophilicity and sustain this characteristic for a long time.

Figure 2.5 Relationship between photocatalytic and hydrophilic properties on TiO_2 -coted surface. (Irie and Hashimoto, 2005)

2.6 Applications of hydrophilic property of TiO₂ film

2.6.1 Self-cleaning surface (Fujishima and Zhang, 2006; Fujishima et al., 2008)

Based on the photocatalytic and hydrophilic properties of TiO₂ surface, gradually adsorbed organic contaminants are decomposed by photocatalytic process, while self cleaning of contaminated-surface could be enhanced when the water, such natural rainfall, are applied to the surface, which water penetrated to the space between the stain and hydrophilic surface TiO₂ and washed off from surface. This technique is obviously of great value, since it can utilize freely available solar light or waste UV emission from fluorescence lamps, save maintenance cost and reduce the use of detergents. The best use of self-cleaning TiO₂ surfaces should be exterior construction materials, since these materials could be exposed to abundant sunlight and natural rainfall. Such materials, including tiles, glass, aluminium siding, plastic films, tent materials, cement, etc. It is not true that a superhydrophilic self-cleaning surface will never turn dirty, since the efficiency of self-cleaning surface was found to be dependent on the relative rate of contamination and decontamination, illumination of sun light and amount of rainfall, which TiO₂ photocatalyst can maintain the surface clean only when the photocatalytic decontamination rate is greater than that of contamination. But, it really trues that such a self-cleaning surface retard the rate of contamination.

2.6.2 Anti-fogging surface (Fujishima et al., 2008)

Fogging of the surface of mirrors and glasses occurs when moist air cools down on these surfaces, forming many water droplets. These droplets, ranging from micrometer to millimeter size, tend either to scatter light or simply to reflect or refract it randomly. On a highly hydrophilic surface, no water droplets are formed which spreads evenly across the surface. If the amount of the water is relatively small, the water layer becomes very thin and evaporates quickly. If the amount of water is large, it forms a sheet like-layer that also has high visual clarity. The first commercial application of this phenomenon has been for automobile slide-view mirrors. In

addition, it has marketed adhesive TiO₂-coated plastic films or TiO₂-containing sprays for the conversion of existing mirrors.

2.6.3 Heat transfer and heat dissipation (Irie and Hashimoto, 2005 and Fujishima, 2008)

Superhydrophilic surfaces may improve the heat transfer accompanied by liquid-vapor phase transition. Takata and coworkers (2005) studied the heat transfer properties of superhydrophilic TiO₂ surfaces. They found that a TiO₂-coated Cu cylinder exhibited excellent heat transfer characteristics in the nucleated boiling regime, and its critical heat flux (a condition where liquid cannot rewet the heater wall because of the rate of vapor production impeding the liquid flow back to the hot surface) was about two times higher than that of the uncoated surface. They also compared the falling-film evaporation on a superhydrophilic surface with that on an ordinary surface which, water was sprayed on the heated surface through nozzles to form a water film. On the superhydrophilic surface, a stable water film was formed than those on an ordinary surface. Since the heat transfer rate increases for thinner water films, the superhydrophilic surface is expected to improve the performance of falling-film evaporators. These workers suggested that the superhydrophilic surface could be an ideal heat transfer surface and would be applicable to various heat transfer phenomena that are affected by surface wettability.

On the other hand, when water vapor pressure is lower than saturated vapor pressure, water evaporates, generating latent heat flux, accompanied by a cooling down of the surrounding atmosphere. Sprinkling a very small amount of water continuously onto the highly hydrophilic TiO₂ surface, effective cooling can be achieved. A very thin water layer with a thickness of approximately 0.1 mm can cover all of the highly hydrophilic TiO₂ material, even though it stands vertically, if only a small amount of water is supplied continuously. This technology is applicable to the building of walls. The TiO₂-coated walls become highly hydrophilic through exposure to solar light and thus the sprinkled water will form a thin layer and be evaporated efficiently from the surface. The evaporation of the water generates latent heat flux, which cools the building surfaces and the surrounding atmosphere. The cooling effect

reduces the usage of air conditioning, saves on energy consumption, and reduces the artificial heat emission.

2.7 Effects of various parameters on hydrophilicity of titanium dioxide

This section discusses the effects of several parameters on hydrophilicity of TiO_2 . The parameters include TiO_2 phase structure, surface hydroxyl group, specific surface area and surface roughness, surface defective site, recombination of electron and hole, band gap energy and surface acidity.

2.7.1 Effect of titanium dioxide phase structure

Yu and coworkers (2002a) studied light-induced superhydrophilicity of mesoporous TiO_2 thin films. Mesoporous TiO_2 (MTiO_2) and TiO_2 thin films were prepared by a modified reverse micellar and a sol-gel method, respectively, followed by dip coating on fused quartz substrate. Both MTiO_2 and TiO_2 films were calcined at 500 °C and 900 °C in order to obtain anatase and rutile phase structure, respectively. MTiO_2 and TiO_2 films in anatase phase structure became hydrophilic faster than MTiO_2 and TiO_2 films in rutile phase structure did. This can be explained by the longer life time of photo-generated electrons and holes in anatase phase structure, resulting in the formation of more oxygen vacancies. Furthermore, the content of hydroxyl groups on the surfaces of MTiO_2 and TiO_2 films in anatase phase structure was greater, so their polarity and hydrophilicity was greater.

Yu and coworkers (2002b) studied the effect of calcination temperatures on photo-induced superhydrophilicity of mesoporous TiO_2 thin films, which were prepared on fused quartz substrate by a sol-gel method, followed by dip coating. Mesoporous TiO_2 thin films were calcined at 500, 700, and 900 °C in order to obtain anatase, mixture of anatase and rutile, and rutile phase structure, respectively. The film that was calcined at 700 °C became hydrophilic at the faster rate because the film was composed of anatase and rutile phases, which was beneficial in enhancing the transfer of photo-generated electrons from the anatase to the rutile phases, thereby reducing the recombination of electrons–holes in anatase phase.

Moreover, the films that were calcined at 700 °C possessed high content of surface hydroxyl group (compared with the films calcined at 900 °C) and high surface roughness (compared with the films calcined at 500 °C).

2.7.2 Effect of hydroxyl groups on surface

Yu and Zhao (2001) prepared TiO₂ thin films by a sol-gel method, followed by coating on soda lime glass substrate. Then the films were soaked in 0.2 M HCl for four days. The thickness of TiO₂ thin films did not affect the water contact angle. Results from XPS analysis indicated that the content of surface hydroxyl groups of TiO₂ thin films after HCl treatment increased and led to a decrease in the water contact angle or enhanced hydrophilicity. The increase in surface hydroxyl groups after the treatment was attributed to the proton-exchange action at the interface of Na in nascent TiO₂ layer (from soda lime glass substrate) with proton (H⁺) from HCl.

Yu and coworkers (2001) added polyethylene glycol (PEG) to the precursor solution during the preparation of porous TiO₂ films via a sol-gel method on soda lime glass substrate. When amount of PEG increased, pore size and specific surface area of TiO₂ increased, leading to an increase in hydroxyl adsorbed content on TiO₂ surface. The hydrophilicity of the film was enhanced because of increasing van der Waals forces and hydrogen bond interaction between water and hydroxyl groups. However, when the amount of PEG exceeded 0.5 g, the hydroxyl content did not change significantly, and the contact angle remained unchanged.

2.7.3 Effect of band gap energy

Jiang and Chen (2004) studied the hydrophilic properties of V₂O₅-TiO₂ thin films, which were prepared on glass substrates by a sol-gel processing and followed dip-coating method. The results showed that the crystallite size of anatase TiO₂ decreased as increased vanadia contents from 46 nm (TiO₂) to 20 nm (1.81 mol% V₂O₅). Before irradiation, the water contact angles of the films were about 34°. After illuminated by sunlight for 40 minutes, the water contact angles of V₂O₅-TiO₂

films drastically fell to 5° , but TiO_2 film that remained unchanged. The improvement of hydrophilicity was attributed to doping of vanadium ion could produce a visible-light response which may change the band gap energy between the conduction and valence bands. Thus, it acquires the capability of absorbing visible light. Moreover, smaller crystal size of TiO_2 after V_2O_5 adding, photo-generated electrons could easier to move to the surface of film with smaller crystal size and produce more oxygen vacancies and defective sites.

Weng and coworkers (2005) investigated the effect of Fe doping on superhydrophilicity of TiO_2 thin films. TiO_2 and Fe-doped TiO_2 thin films were prepared by spray pyrolysis deposition technique on glass substrate. The hydrophilicity of thin films was evaluated by the contact angle of water under illuminated of Xenon lamp. The doping of Fe enhanced the hydrophilicity of the film, which was attributed to the decrease in the band gap energy of the TiO_2 and, consequently, the increase in ability to absorb photon in visible spectrum.

Li and coworkers (2007) studied the effects of vanadium incorporation on hydrophilic properties of TiO_2 film. $\text{Ti}_{1-x}\text{V}_x\text{O}_2$ ($x=0.05-0.2$) films were prepared by a sol-gel method and followed dip-coating. After daylight illumination, the contact angle decreases greatly with increasing of the x values, which $\text{Ti}_{1-x}\text{V}_x\text{O}_2$ films with $x=0.1-0.2$ showed super-hydrophilic property. The increasing of surface roughness, lattice distortion that was caused by partial substitution of V^{4+} ions for Ti sites and V-incorporation narrows band gap of $\text{Ti}_{1-x}\text{V}_x\text{O}_2$ were beneficial to the super-hydrophilicity.

2.7.4 Effects of defective site and inhibition of recombination of photo-generated electrons and holes

Jiang and Gao (2002) investigated the effects of Fe doping on photo-induced hydrophilicity of TiO_2 thin films. TiO_2 and Fe-doped TiO_2 thin films were prepared by a sol-gel method followed dip coating on soda lime glass substrates. The best hydrophilicity was achieved with TiO_2 film that was doped with 5 mol% Fe.

Increasing the amount of Fe doping reduced the hydrophilicity of the film because Fe_2O_3 itself did not exhibit hydrophilicity. An enhancement in hydrophilicity of TiO_2 surface was related to the preferential adsorption of water on the defective site on TiO_2 , which increased with Fe doping. Furthermore, photo-generated electrons in the doped film accumulated in the conduction band of Fe_2O_3 whereas holes accumulated in the valence band of TiO_2 effectively. Therefore, the recombination of electrons and holes was retarded and the hydrophilicity was greatly enhanced.

Lee and coworkers (2003) investigated the TiO_2 thin films that were doped with Al, W, and Al + W (1:1) in order to make the photoactivity of the surface suitable for hydrophilicity. TiO_2 thin films were prepared using the dip-coating method on soda lime glass and quartz. Doping of Al + W had the highest resistance to conversion from hydrophilic to hydrophobic state with contact angle of water remaining at 25° . The original hydrophilic state was restored within three hours with contact angle of water at 5° . From XPS analysis, the concentration of Ti^{3+} compared with Ti^{4+} in undoped, Al-doped, W-doped, and Al + W co-doped were 58.63%, 46.45%, 57.19%, and 63.81%, respectively. The concentration of Ti^{3+} on TiO_2 surface was a major factor influencing hydrophilicity. The same trend was observed in both soda lime glass and quartz substrate. Furthermore, hydrophilicity of TiO_2 thin films also depended on traps for electrons or holes and surface acidity.

Du and coworkers (2005) investigated the effects of Mo doping on hydrophilicity of TiO_2 thin films which were induced by high temperature annealing. TiO_2 and Mo-doped TiO_2 thin films were prepared by a sol-gel method and coated on soda lime glass substrates. After calcination at 400°C for one hour, all the Mo-doped films showed relatively smaller water contact angle than pure TiO_2 film did. The 0.75 wt% Mo-doped TiO_2 film exhibited superhydrophilicity. Regarding the effect of heating time at 400°C , the 0.75 wt% Mo-doped TiO_2 film reached the contact angle of zero after half an hour, while the contact angle for other films were below 15° but never reached zero even when heating time was increased. Doping of Mo has dual effects on hydrophilicity of TiO_2 films. On the one hand, the number of defect site (Ti^{3+}) increased with Mo doping. As a result, water molecules could occupy those

oxygen vacancies to produce surface hydroxyl groups and make the surface hydrophilic. On the other hand, MoO_3 itself does not exhibit hydrophilicity, so hydrophilicity decreased when the doping content exceeded 0.75 wt%.

Yu and coworkers (2006) studied an enhancement of photo-induced superhydrophilicity of TiO_2 thin films by Fe doping. Fe-doped TiO_2 thin films were prepared on soda lime glass pre-coated with SiO_2 layer by a sol-gel method, followed by dip coating. TiO_2 thin films that were doped with Fe at 0.05-0.2 atomic% showed the best photo-induced superhydrophilicity. This may be due to the fact that a small amount of Fe^{3+} ions acted as traps for both photo-generated electrons and holes and inhibited the recombination of electrons and holes. A lowering of hydrophilization rate was expected when the amount of Fe became too large because Fe mainly acted as recombination centers. When being stored in the dark, all Fe-doped films exhibited slow conversion rate from hydrophilicity to hydrophobicity than pure TiO_2 film because Fe-doped films not only contained highly surface hydroxyl group content but also small crystallite size, favoring the adsorption of water molecules and reducing the rate of conversion from hydrophilic to hydrophobic state.

Sharma and coworkers (2006) studied the effects of Ni doping on photo-induced hydrophilicity of TiO_2 thin films. Pure and Ni-doped TiO_2 thin films were prepared by a sol-gel method, followed dip coating on soda glass substrates. Pure TiO_2 film reached a contact angle of zero after one hour of illumination. For Ni-doped films, 10 mol% Ni-doped films exhibited the best hydrophilicity by reaching contact angles of zero after 20 minutes of illumination. An enhancement in hydrophilicity of TiO_2 surface was related to the preferential adsorption of water on the defective site on TiO_2 , which increased with Ni doping. Furthermore, the recombination of electrons and holes was retarded and the hydrophilicity was greatly enhanced.

Yuan and coworkers (2007) studied the effects of doping of Fe and Cr on hydrophilic properties of anatase TiO_2 films. The TiO_2 films were prepared by a modified sol-gel method and were doped by phodeposition of Fe_2O_3 and Cr_2O_3 .

Before illumination, the Fe- and Cr-doped films had smaller contact angle (30° and 35° , respectively) than pure TiO_2 film (60°). After three hours of UV illumination, the contact angle reached 0° for Fe- and Cr-doped films and reached 28° for pure TiO_2 film. That is, the doped films exhibited good hydrophilicity. The improvement in hydrophilicity was a result of the electrons reacting with lattice metal ions (Ti, Fe, and Cr) to form defective site.

2.8 Effect of metal loading to TiO_2 on photocatalytic activity of titanium dioxide

Li and coworkers (2001) studied photocatalytic activity of tungsten-doped TiO_2 which, were prepared by a sol-gel method. The photoactivity was evaluated by photodegradation of methylene blue under visible light irradiation. The activity of tungsten-doped TiO_2 was significantly higher than that of pure TiO_2 . The optimal content of WO_x in TiO_2 was found to be 3 mol%. In small amount, doping of tungsten oxide into TiO_2 could hinder the recombination of photo-generated electrons and holes. On the other hand, when the content of tungsten oxide was higher than its optimal amount, tungsten oxide would become a recombination center instead. Furthermore, doping of tungsten oxide into TiO_2 could shift the light absorption band from near UV range to the visible range.

Rampaul and coworkers (2003) reported the photocatalytic activity of titania and tungsten-doped TiO_2 which were prepared by a sol-gel method, followed dip coating on glass substrates. The photoactivity of the films was measured by photodegradation of stearic acid on the film surface. The most active photocatalyst was the 2% tungsten doped TiO_2 film with three coats owing to WO_3 acting as an effective separation center for the electrons and holes, resulting in the photo-generated electron being transferred to the surface rather than undergoing bulk recombination.

Ke and coworkers (2008) studied the photocatalytic activity of WO_3/TiO_2 nanocomposite particles, which were prepared by a hydrothermal method and then were calcined a temperature in the range of $450\text{--}900^\circ\text{C}$. The activity for RhB photodegradation of equimolar WO_3/TiO_2 composite that was calcined at 550°C was

significantly higher than that of pure TiO_2 and just slightly lower than that of Degussa P25. This may be attributed to the more efficient separation of photo-generated charge carriers, light absorption and higher surface acidity.

Tian and coworkers (2008) studied photocatalytic activity of W-doped TiO_2 photocatalyst. Nanosized W- TiO_2 photocatalyst were prepared by a hydrothermal method and their photocatalytic activity was evaluated by photodegradation of methyl orange in aqueous solution. The results showed that the photocatalytic activities of W-doped TiO_2 increased as the synthetic temperature was increased from 120-180 °C, but decreased significantly when further to 210 °C. The main reason may be attributed to the influence of surface area, the crystallization and aggregation of crystallites. Moreover, TiO_2 that containing 2.0 mol% and was prepared at synthetic temperature of 150 °C obtained the highest photocatalytic activity because the doping of tungsten helps in trapping of photo-generated electrons. So, the charge recombination was inhibited. However, tungsten could act as recombination center for electron-hole pairs at too high loading.

He and coworkers (2002) investigated the effects of Ag doping on the microstructure and photocatalytic activity of TiO_2 films, which were prepared by a sol-gel method. With a suitable amount of 2-4 mol%, doping of Ag effectively increased the photocatalytic activity of TiO_2 films. This can be explained in two reasons; firstly, a decrease in anatase grains size and an increase in specific surface area of TiO_2 films. Secondly, an enhancement in the separation of charge pairs and inhibit of their recombination by Ag dopant. On the other hand, when doping of Ag exceeded 2-4 mol%, holes in the interfacial region of TiO_2 films may be trapped by Ag particles with relatively negative charge, so photocatalytic activity of Ag- TiO_2 was depressed.

Xin and coworkers (2005) studied photocatalytic activity of Ag- TiO_2 nanoparticle films. Ag- TiO_2 nanoparticles were synthesized by a sol-gel method and then were prepared in form of organic pastes before fabricated on ITO glass by means of doctor-blade. Photocatalytic activity of Ag- TiO_2 nanoparticle films was evaluated

by photocatalytic degradation of rhodamine B. The highest photocatalytic activity was observed at TiO₂ that containing 3 mol% Ag. This was attributed to appropriately doped and deposited Ag species on the surface of TiO₂ can capture the photo-generated electrons and holes. However, when the content of Ag exceed 3 mol%, the amount of active sites reduced and excessive Ag dopant can overlies on the TiO₂ surface, which lead to decreasing in photocatalytic activity.

Xin and coworkers (2005) studied the simultaneous doping and deposit Ag on photocatalytic activity of TiO₂, which Ag-TiO₂ catalysts were prepared by a sol-gel method. Photocatalytic activity of Ag-TiO₂ was investigated by photocatalytic degradation of rhodamine B solution. The PL and SPS intensities of Ag-TiO₂ photocatalysts were decreased with increasing the Ag content, indicating that the Ag dopant could effectively inhibit the recombination of the photogenerated electrons and holes. The appropriate content of Ag (about 3-5 mol%) could greatly enhance the activity of the photocatalysts. However, the active sites for capturing the photogenerated electrons reduced, while the Ag content exceeded 5 mol%.

Li and coworkers (2004) studied photocatalytic activity of TiO₂-Cu₂O particles, which were prepared by a novel electrochemical method and their photocatalytic activity was tested by photodegradation of brilliant red dye solution. The results were found that the catalytic efficiency increased by Cu₂O depositing on TiO₂ but it decreased at higher Cu₂O loadings, which the highest degradation was obtained for the composite containing 3wt% Cu₂O. This can be explained by Cu₂O can accelerate the transferring of electrons to adsorbed oxygen, which be the rate limiting step in photocatalysis. Thus, the recombination of electrons and holes was decrease.

Xia and coworkers (2008) studied the effect of copper loading on photocatalytic activity of rutile TiO₂ which were prepared by a sol-gel method. Photoactivity of Cu-TiO₂ was tested by degradation of aqueous brilliant red X-3b solution. TiO₂ that containing 2% copper showed the best photocatalytic activity, which was 3 times that undoped rutile TiO₂. This was attributed to the decreasing in

the recombination of electrons and holes on TiO₂ surface. Because Cu²⁺ is an effective acceptor for electrons, it contests for electrons with the holes. However, excessive copper was deposited on TiO₂, more Cu(OH)²⁺ would be formed. Cu(OH)²⁺ had a greater adsorption to the incidence light. This high adsorption decreased the light energy irradiating on the surface of TiO₂ and the removal efficiency of X-3B was decreased.

Xin and coworkers (2008) studied the effect of Cu-doped TiO₂ nanoparticles on photocatalytic activity, which were prepared by a sol-gel method. The 0.06 mol% Cu-TiO₂ that was calcined at 400 °C for four hours showed the highest RhB degradation rate because the appropriate amount of oxygen vacancies and doped Cu effectively captured the photo-generated electrons, so the recombination of the electrons and holes was inhibited. At high Cu doping (> 0.06 mol%), the excessive oxygen vacancies and Cu species became the recombination centers of photo-generated electrons and holes. Furthermore, at high Cu doping, excessive p-type Cu₂O also reduced photocatalytic activity of Cu-TiO₂ photocatalyst.

Xu and coworkers (2008) studied copper-deposited TiO₂ photocatalysts, which TiO₂ powders were prepared by a sol-gel method and followed deposition of copper (0-0.32 mol%) on TiO₂ surface by photoreduction method. The photocatalytic activity of Cu₂O-TiO₂ was evaluated by photodegradation of methylene blue under UV light irradiation. The results from XPS and AES revealed that all copper existed in the Cu(I) state. The highest photocatalytic degradation was obtained for 0.16% Cu₂O-TiO₂, this was attributed to Cu₂O can trap electrons and transferred to the surrounding adsorbed O₂, while the holes oxidize OH⁻, H₂O, or the organics, and thereby prevent the electron-hole recombination. Thus, the photocatalytic activity of methylene blue was enhanced. However, when copper-deposited content reached to 0.32%, the photocatalytic activity was lower than that TiO₂. Because, the excessive of Cu₂O deposited on TiO₂ may screen the surface of TiO₂ from UV light.

CHAPTER III

MATERIALS AND METHODS

3.1 Chemicals

The details of chemicals used in this study are listed in Table 3.1

Table 3.1 List of chemicals were used in this studied.

Chemicals, Purity	Manufacturers
Titanium isopropoxide, 97 %	Sigma-Aldrich
Nitric acid, 69-70 %	J. T. Baker
Hydrofluoric acid, 49 %	QRëC™
Silver nitrate, 99+ %	Sigma-Aldrich
Ammonium metatungstate, 99.98 %	Sigma-Aldrich
Copper nitrate, 98-103 %	Fluka
Ammonium molybdate, 99.98 %	Sigma-Aldrich
Ethanol, 99.9 %	Merk
Acetone, 99.5 %	QRëC™

3.2 Preparation of the thin films

This section describes the synthesis of TiO₂ and metal loaded-TiO₂ sol using a sol-gel processes and preparation of the thin films by a dip-coating technique.

3.2.1 Preparation of TiO₂ sol

Titanium dioxide sol was synthesized using a sol-gel process, and titanium isopropoxide was employed as a precursor. Firstly, 7.33 mL of 70% nitric acid was added to 1000 mL of distilled water. While the acidic solution was stirred, 83.5 mL of titanium isopropoxide was slowly added. After that, the white suspension was immediately occurred. The suspension was continuously stirred at room temperature for about 3 days until clear sol was obtained. The sol was placed in dialysis tubing (cellulose membrane, Spectrum Laboratories Inc, USA) and then was submerged in distilled water using a ratio of 100 mL of sol per 700 mL of distilled water. The water was changed daily until the pH of permeate reached to 3.3. The resulting product was dialyzed TiO₂ sol which was kept at low temperature.

3.2.2 Preparation of metal-loaded TiO₂ sol

The amount of metal in the sample was in a term of a molar percentage of metal. The concentration of TiO₂ particles in the sol was obtained after TiO₂ sol was dried at 110 °C for 24 hours and calcined at 350 °C for two hours.

To prepare Ag-TiO₂ sol, the desired amount of silver nitrate was dissolved in 10 mL of deionized water and was then added dropwise to 140 mL of TiO₂ sol (pH 3.3) under vigorous stirring for one hour. The amount of silver added was in the range of 0.1-5.0 mol% silver.

To prepare W-TiO₂ sol, the pH of TiO₂ sol was adjusted to 1.0 by 1 M nitric acid. The desired amount of 0.2 M ammonium metatungstate solution (pH 2.5) was added dropwise to 140 mL of TiO₂ sol under vigorous stirring and the stirring continued for six hours. The amount of tungsten added was in the range of 0.1-1.5 mol% tungsten.

To prepared Cu-TiO₂ sol, the pH of TiO₂ sol was adjusted to 2.5 by 1 M nitric acid. The desired amount of 0.2 M copper nitrate solution (pH 2.5) was added dropwise to 140 mL of TiO₂ sol under vigorous stirring and the stirring

continued for one hour. The amount of copper added was in the range of 0.1-5.0 mol% copper.

To prepared Mo-TiO₂ sol, the pH of TiO₂ sol was adjusted to 2.0 by 1 M nitric acid. The desired amount of 0.2 M ammonium molybdate solution (pH 2.5) was added dropwise to 140 mL of TiO₂ sol under vigorous stirring and the stirring continued for two hours. The amount of molybdenum added was in the range of 0.1-1.0 mol% molybdenum.

For a comparison the pH, TiO₂ sol without metal loading was adjusted to the same value for each metal. The sol was dried and the powder was fired in order to obtain the reference samples.

3.2.3 Preparation of TiO₂ and metal-loaded TiO₂ thin films

TiO₂ and metal loaded-TiO₂ thin films were coated on soda lime glass plates (Menzel-Glaser, Germany) using a dip-coating technique. Prior to coating, glass plates were cleaned with a detergent solution in an ultrasonic bath for 30 minutes, and were washed with ethanol and then acetone. The glass plates were submerged in the sol and were held for 5 minutes. Then a motor withdrew the plates at a speed of 3.67 cm/min. The as-prepared films were calcined in a box furnace under stagnant air at 350 °C with a heating rate of 10 °C/min for two hours. The as-calcined films had a hydrophilic surface with a water contact angle of ca. 5°. Before further experiment, the films were stored in the dark place for four weeks in order to increase the water contact angle on the surface.

3.3 Characterization of the thin films

In order to determine physical and chemical properties of the films, various characterization techniques were employed and the results were discussed in this section.

3.3.1 X-ray diffractometry (XRD)

XRD was employed to identify crystal phase and crystallinity of sample. The equipment was a SIEMENS D5000 X-ray diffractometer with Cu K α radiation using Ni filter and operating at 20 kV and 20 mA. The amount of the sample used was calculated in order to obtain the same amount of TiO₂ in each sample. The diffraction patterns were scanned in the 2 θ range of 20-80° with a resolution of 0.02°. The average crystallite sizes of TiO₂ were calculated by Debye-Sherrer's formula from the line broadening of anatase (110) peak according to Equation 3.1

$$D = \frac{K\lambda}{\beta \cos \theta} \quad (3.1)$$

where D is crystallite size (Å)

K is crystallite shape factor (0.9)

λ is X-ray wavelength (1.5418 Å for Cu K α)

θ is the diffraction angle of crystal plane (degree)

β is X-ray diffraction broadening (radian)

3.3.2 X-ray photoelectron spectroscopy (XPS)

XPS surface analysis was performed using a Kratos Amicus X-ray photoelectron spectroscope. The XPS spectra was obtained using Mg K α X-ray source at 20 mA and 10 keV with a resolution of 0.1 eV. The operating pressure was approximately 5 x 10⁻⁶ Pa. A wide-scan survey spectrum was collected for each sample in order to determine the elements present on surface. All binding energies were calibrated for the correction of charging shift with C 1s photoemission peak at 284.6 eV. Photoemission peak area was determined after smoothing and background subtraction using a linear routine. Deconvolution of complex spectra were performed by fitting with Gaussian (70%)-Lorentzian (30%) shape using VISION 2 software equipped with the XPS system.

3.3.3 Inductively coupled plasma optical emission spectroscopy (ICP-OES)

The metal content in a sample was measured with a Perkin Elmer Optima 2100 DV spectrometer. To digest the samples, approximately 0.01 grams of the sample was dissolved with 8 mL of 49% hydrofluoric acid in a plastic beaker. The mixture was stirred for two hours and then diluted to 100 mL with deionized water in a plastic volumetric flask. Blank sample was prepared from a solution of 49% hydrofluoric acid that underwent the same dilution procedure as the sample.

3.3.4 Nitrogen physisorption

Specific surface area was measured by nitrogen adsorption in a continuous flow method at liquid nitrogen temperature using Micromeritics ChemiSorb 2750 Pulse Chemisorption System instrument. A mixture of 30 vol% N₂ in helium was employed as the carrier gas. Before each experiment, approximately 0.2 gram of samples was placed in a glass tube and was heated at 200 °C for one hour under helium gas with a flow rate of 15 mL/min to remove moisture.

3.3.5 Atomic force microscope (AFM)

The surface morphology and roughness of the film sample was characterized using a MultiMode atomic force microscope from Digital Instruments, which operated in the tapping mode at room temperature. AFM analysis permitted the quantification of the roughness in terms of the root mean square values (RMS).

3.3.6 UV-Visible spectroscopy (UV-Vis)

The light absorption characteristics of the films were measured using a lampda 650 UV-Vis spectrophotometer from Perkin Elmer in transmittance mode. The transmission spectra were scanned in the range of 300–700 nm with a step size of 1 nm. A clean glass plate was used as a background for reference.

3.3.7 Temperature-programmed desorption (NH₃-TPD)

Temperature programmed desorption (TPD) using NH₃ as a probe molecule was performed by a Micromeritic ChemiSorb 2750 automated system attached with ChemiSoft TPx software. The amount of NH₃ adsorbed on the surface was determined by a thermal conductivity detector. Approximately 0.1 gram of a sample was put in a quartz tube, which was placed in a temperature-controlled furnace. Helium gas was fed through sample at a flow rate of 15 mL/min. The sample was heated to 350 °C with a heating rate of 10 °C/min and the temperature was held for two hours to remove moisture. Then the sample was cooled down to 30 °C. After that, 15 vol% NH₃ in helium was fed through sample at a flow rate of 15 mL/min instead of helium, and the flow was held for one hour. Subsequently, helium gas was fed through the sample for two hours. Finally, the sample was heated from 30 °C to 600 °C with a heating rate of 10 °C/min. The signal from this step was recorded every one second.

3.3.8 Photoluminescence spectroscopy (PL)

To study the recombination behavior of photo-generated electron and holes, photoluminescence spectra were carried out at room temperature by a Perkin Elmer LS55 fluorescence spectrophotometer using a Xenon lamp as an excitation light source. The sample (0.14 g) was compressed in a holder. The scan was performed in the range of 350-550 nm using an excitation wavelength of 300 nm with emission and excitation slit widths of 5.0 nm.

3.3.9 Photo-induced hydrophilicity of thin films

The hydrophilicity of the films was evaluated by measuring the contact angle of a water droplet on the film surface by a contact angle meter (TANTEC Inc., USA). Two backlight fluorescence bulbs (15 W PHILIPS, Thailand) were used as a light source with average light irradiance of 0.67 mW/cm². The distance between a light source and the film surface was 15 cm. To measure the contact angle, the film was placed on a stage. Then the stage was raised to bring the film into contact with a

water droplet (approximately 0.3 μL). After that, the CCD video camera captured the picture of a water droplet on the film surface. The contact angle was calculated using trigonometry formula with TANTEC program. Five points of water droplet were place in different positions on the film surface and used as average contact angle. To study the ability to retain the hydrophilic properties of the films after removal of UV irradiation, the films were kept in the dark place and take out to measurement contact angle at any times.

3.3.10 Temperature programmed reduction (TPR)

To study the reduction behavior of a sample, temperature programmed reduction (TPR) was performed by a Micromeritic ChemiSorb 2750 automated system attached with ChemiSoft TPx software. Approximately 0.05 gram of the sample was put in a quartz tube, which was placed in a temperature-controlled furnace. Nitrogen gas was fed through sample at a flow rate of 25 mL/min. The sample was heated to 200 $^{\circ}\text{C}$ with a heating rate of 10 $^{\circ}\text{C}/\text{min}$ and the temperature was held for one hour to remove moisture. Then the sample was cooled down to 30 $^{\circ}\text{C}$ and 10 vol% H_2 in argon was fed through sample at a flow rate of 25 mL/min instead of nitrogen. The sample was heated from 30 $^{\circ}\text{C}$ to 800 $^{\circ}\text{C}$ with a heating rate of 10 $^{\circ}\text{C}/\text{min}$. The hydrogen consumption was measured quantitatively by a thermal conductivity detector and the signal from this step was recorded every one second.

CHAPTER IV

RESULT AND DISCUSSION

This chapter presents the results and discussion on the effect of loading of silver, tungsten, copper, and molybdenum on properties of TiO₂ thin film.

4.1 Effect of silver loading to TiO₂ thin film

4.1.1 Phase structures of Ag-TiO₂

The bulk crystalline phase of Ag-TiO₂ samples were investigated using X-ray diffractometer (XRD). In Figure 4.1 presents XRD patterns of Ag-TiO₂ powder after calcined at 350 °C under stagnant air for 2 hours. The amounts of silver loading were 0.1, 0.5, 1.0, 3.0, and 5.0 mol% respectively. The major phase structure of TiO₂ was anatase, which were observed at 2θ of about 25.3° (101), 37.9° (004), 47.9° (200), 54.0° (105), 62.8 (204) and 69.2° (116) respectively. Small amount of rutile phase was observed at 2θ of about 27.3° (110) and 33.6° (101). The weak peak at 2θ of about 30° was assigned to brookite phase (121), which was a transitional phase from anatase to rutile in the healing processes (Shen et al., 2008). After silver loading, the main phase structure of TiO₂ still unchanged but the intensity of the diffraction patterns decreased remarkably, which correlated with crystallinity of TiO₂. This was indicated that the loading of silver suppressed the crystallization of TiO₂. Furthermore, no diffraction peak corresponding to silver oxide or metallic silver were detected in any samples, this may be due to low amount of silver species or uniformly dispersed on TiO₂ surface.

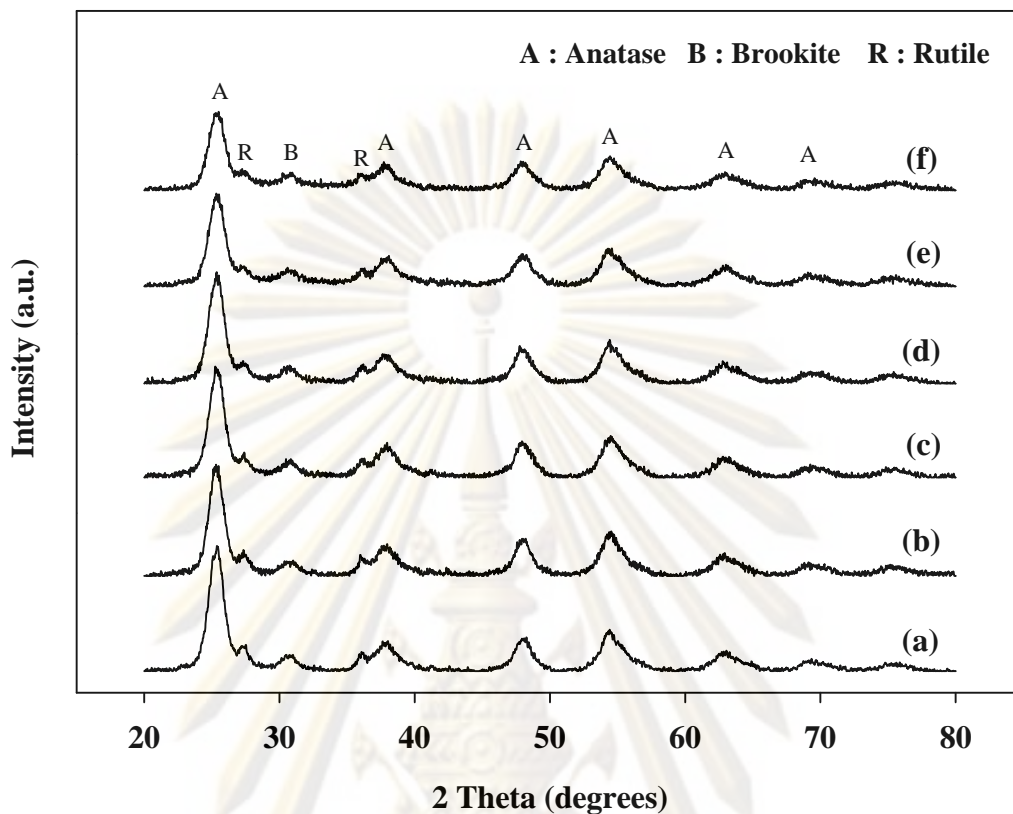

Figure 4.1 X-ray diffraction patterns of Ag-TiO₂ at various amount of silver loading when (a) 0.0 mol%, (b) 0.1 mol%, (c) 0.5 mol%, (d) 1.0 mol%, (e) 3.0 mol%, and (f) 5.0 mol% Ag.

Average crystallite size of anatase was calculated from the strongest peak of XRD pattern at 2θ about 25.3° (101) using Scherrer's formula. The results were listed in Table 4.1. The crystallite size of TiO₂ slightly decreased with increasing of silver loading, which indicating that silver species affect on the grain growth of anatase TiO₂. This was described that, the radius of Ag⁺ (126 pm) is much larger than that of Ti⁴⁺ (68 pm). So, silver ions unable enter into the lattice of TiO₂ to form a stable solid solution and dispersed on TiO₂ surface. In the other word TiO₂ particles will be separated by Ag⁺ ions (He et al., 2002 and Zheng et al., 2007). During calcination process, the silver species became a barrier for rearrangement of Ti⁴⁺ and O²⁻ ions in anatase grain boundaries (Yu et al., 2005). Therefore, the anatase growth rate was suppressed and led to smaller crystallite size.

Table 4.1 Crystallite size of anatase in Ag-TiO₂ at various amount of silver loading.

Amount of silver loading (mol%)	Crystallite size (nm)
0.0	6.4
0.1	6.5
0.5	6.2
1.0	6.3
3.0	5.8
5.0	4.9

4.1.2 Oxidation state of silver species in Ag-TiO₂

Figure 4.2 shows Ag 3d XPS spectra of Ag-TiO₂ that contained 5.0 mol% Ag. It was observed that, the Ag 3d spectra consisted of two peaks spin-orbital splitting photoelectron, which corresponds to Ag 3d_{3/2} and Ag 3d_{5/2}. As in previous studied, the binding energy of Ag 3d_{5/2} for AgO, Ag₂O, and Ag are 367.0, 367.7, and 368.2 eV respectively (Xin et al., 2005). As seen in Figure 4.2, after the Ag 3d_{5/2} peak was deconvoluted, two components of silver species were revealed at the binding energies of 367.6 eV and 368.1 eV. These were assigned to Ag⁺ and Ag⁰. Therefore, it was clearly indicated that, Ag⁺ and Ag⁰ were existence in form of Ag₂O and metallic silver.

4.1.3 Silver content in Ag-TiO₂

The amount of silver contents in Ag-TiO₂ samples were determined using inductively coupled plasma optical emission spectroscopy (ICP-OES) and the results were listed in Table 4.2. As seen in Table 4.2, the real mole percentages of silver were found in Ag-TiO₂ samples was lower than that the expected values.

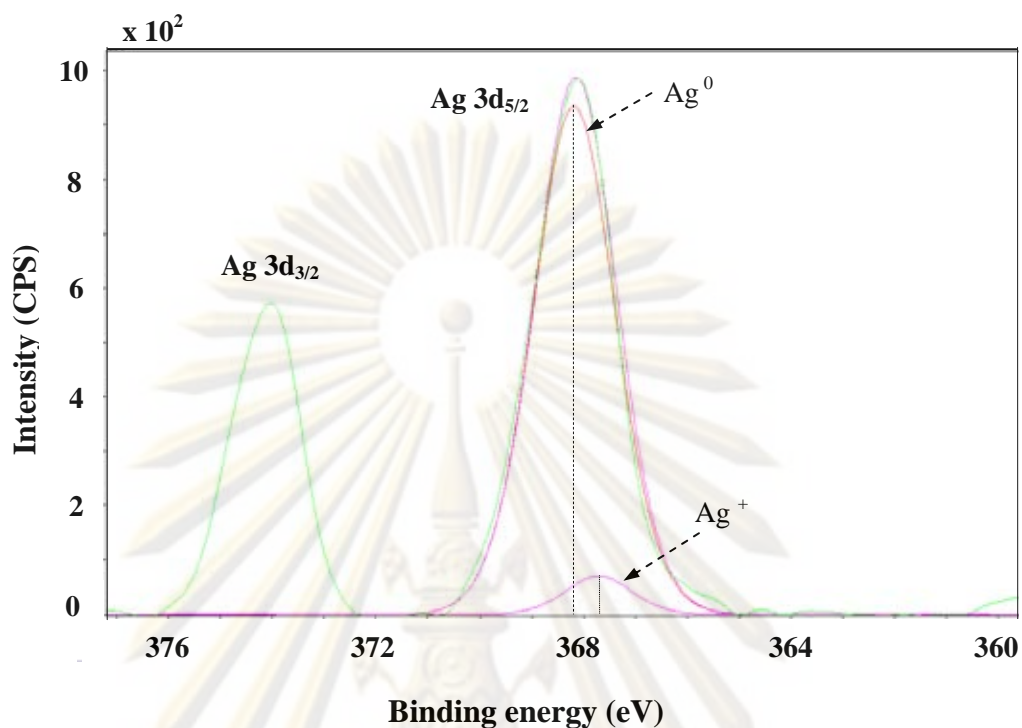

Figure 4.2 Ag 3d XPS spectra of Ag-TiO₂ that contained 5.0 mol% Ag.

Amount of silver loading (mol%)	Amount of silver from ICP (mol%)
0.1	0.033
0.5	0.226
1.0	0.618
3.0	2.717
5.0	5.033

4.1.4 Specific surface area of Ag-TiO₂

The most common procedure for determining surface area of a solid is based on adsorption and condensation of nitrogen at liquid nitrogen temperature using static vacuum procedure. This method is also called BET (Brunauer Emmett Teller) method. Specific surface areas of Ag-TiO₂ at various amount of silver loading were listed in Table 4.3. Surface areas of Ag-TiO₂ were in the range of 98.6-109.0 m²/g. The loading of silver did not have a significant effect on the specific surface area of Ag-TiO₂.

4.1.5 Surface morphology of Ag-TiO₂ thin films

AFM was used to characterize the morphology and uniformity of film surface. Figure 4.3 shows AFM images of Ag-TiO₂ film surface that contained various amount of silver. It was observed that, all films had a uniform surface. The loading of silver into TiO₂ did not have a significant effect on the grain size of TiO₂. Analysis of AFM images revealed that, the average roughness of the Ag-TiO₂ films surface appeared in the range of 2.303-2.807 nm (see Table 4.4).

Table 4.3 Specific surface area of Ag-TiO₂ at various amount of silver loading.

Amount of silver loading (mol%)	Specific surface area (m ² /g)
0.0	107.5
0.1	106.1
0.5	109.0
1.0	104.9
3.0	107.5
5.0	98.6

3.0	2.618
5.0	2.807

4.1.6 Light absorption characteristic of Ag-TiO₂ thin films

Figure 4.4 shows UV-Vis absorption spectra of Ag-TiO₂ films deposited on glass surface in wavelength range of 300-700 nm. All films showed transmittance of light over 70 % entire visible region. The fast decreased in transmittance below 380 nm was due to absorption of light, which was caused by the excitation of electrons from the valance band to conduction of TiO₂ (Yu et al., 2002). When increased of silver loading, the transmittance of Ag-TiO₂ films decreased which was caused by the scattering of light from silver species. To calculate the band gap energy of Ag-TiO₂ film, the graph of $(-2.303h\nu \log T)^{1/2}$ versus $h\nu$ was plotted and extrapolated in a linear part leading to the band gap energy (see in APPENDIX D). It was found that the band gap energies of TiO₂ and TiO₂ films that contained silver of 0.1, 0.5, 1.0, 3.0, and 5.0 mol% were 3.24, 3.22, 3.20, 3.22, 3.44, and 3.42 respectively.

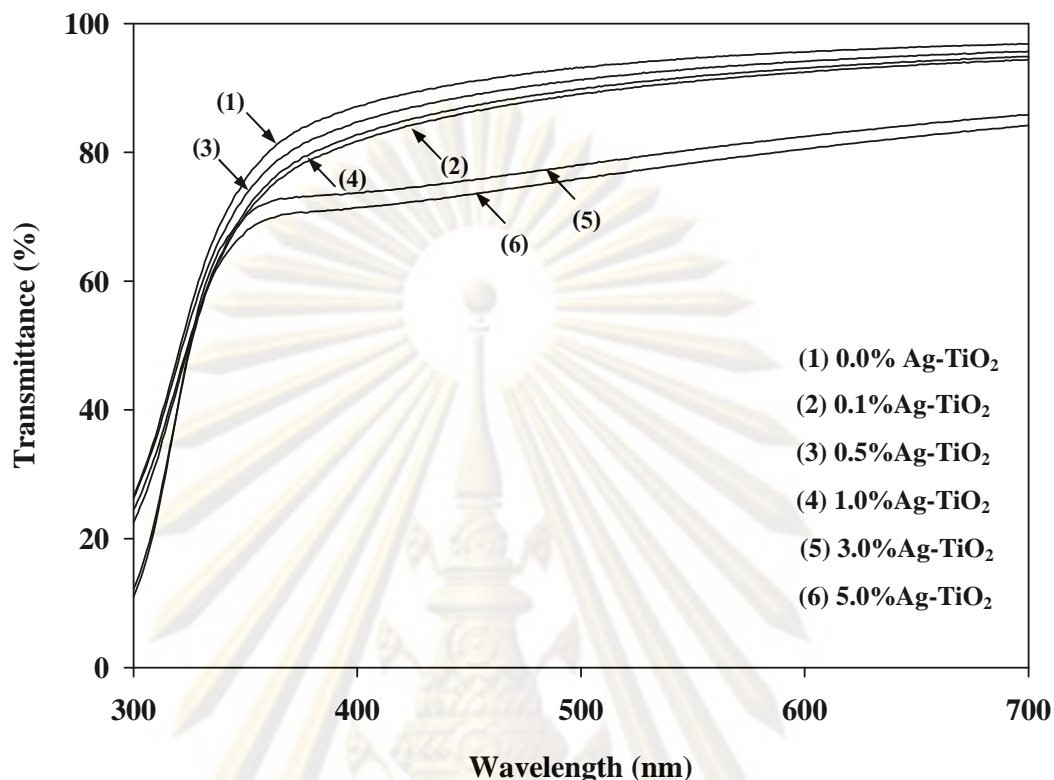

Figure 4.4 UV-Vis spectra of Ag-TiO₂ thin films deposited on glass surface.

4.1.7 Surface acidity of Ag-TiO₂

Temperature-programmed desorption (TPD) of probe molecules like ammonia and pyridine is a popular method for determining the acidity of solid catalysts as well as acid strength sites (Yang et al, 2005). In this investigation, the acidity measurement was carried out using NH₃-TPD. In Figure 4.5 presents NH₃-TPD profiles of Ag-TiO₂ at various amount of silver loading. There was only one asymmetric broad peak on the NH₃-TPD profiles of all the samples and the peak temperatures were ranged between 50 and 600 °C, indicating that the acid sites on surface were the weak and strong strength (Yang et al, 2005 and Yoon et al., 2007). Analysis the total acid sites of Ag-TiO₂ from NH₃-TPD profiles were listed in Table 4.5. The loading of silver reduced the total number of acid sites on Ag-TiO₂ surface.

Figure 4.5 NH_3 -TPD profiles of Ag-TiO_2 at various amount of silver loading.

0.1	23.48
0.5	23.88
1.0	22.21
3.0	21.04
5.0	19.45

4.1.8 Photoluminescence spectra of Ag-TiO₂

The photoluminescence (PL) emission spectra have been widely used to investigate the efficiency of charge carrier trapping, immigration and transfer, and to understand the fate of electron-hole pairs in semiconductor particles (Li et al., 2001). Since PL emission mainly results from the recombination of photo-generated electrons and holes (Yu et al., 2003). The lower PL intensity indicated that the decreasing in the recombination rate. In Figure 4.6 shows PL spectra of Ag-TiO₂ at various amount of silver loading. It was observed that, PL spectra exhibited two emission peaks at the wavelength of about 420 and 485 nm. The former peak was due to free excitation emission of TiO₂ and the latter peak was due to the surface state such as Ti⁴⁺-OH (Nagaveni et al., 2004). With increased silver loading, PL intensity significantly decreased. This was described on the basis of metal/semiconductor heterojunctions that, Schottky barriers are formed at contact region of two materials (see Figure 4.7) (Linsebigler et al., 1995). After Ag-TiO₂ being irradiated, Schottky barriers facilitate the electron transfer from TiO₂ (with high Fermi level) to Ag (with low Fermi level) (Hou et al., 2008 and Zheng et al., 2008). Therefore, the photo-generated electron-hole pairs were effectively separated rather than undergoing recombination. This reason was caused the decreasing in PL intensity after the loading of silver to TiO₂.

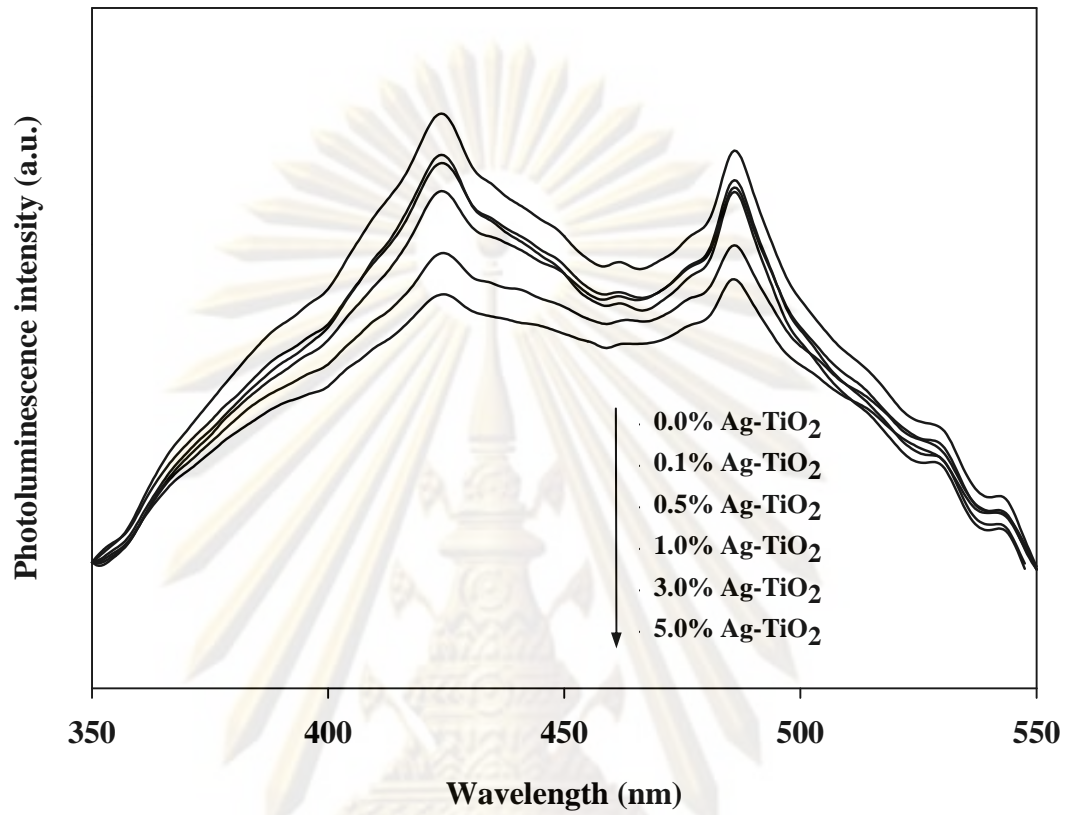

Figure 4.6 PL spectra of Ag-TiO₂ at various amount of silver loading.

Figure 4.7 Charges separation at interfacial of Ag-TiO₂.

4.1.9 Photo-induced hydrophilicity of Ag-TiO₂ films

In Figure 4.8 shows the changes in water contact angle of Ag-TiO₂ films after UV irradiation for 3 hours. Before irradiation, all films had the initial contact angle about 17-21 degrees. In order to compare the effect of silver loading to the change of water contact angle, the initial contact angle of the films should be identical. Thus, the normalized contact angle, which is the angle of water droplet at any times to the initial contact angle of own films was used to consider. In Figure 4.9 shows the changes in normalized contact angle of Ag-TiO₂ films after UV irradiation for 3 hours. As seen in Figure 4.9, when increased silver loading, the decreasing of water contact angle of Ag-TiO₂ films faster than that TiO₂ film. Especially for 3.0-5.0% Ag-TiO₂ films showed the fastest time to decrease the water contact angle. Thus, TiO₂ films that contained 3.0-5.0 mol% silver possessed the best hydrophilic property.

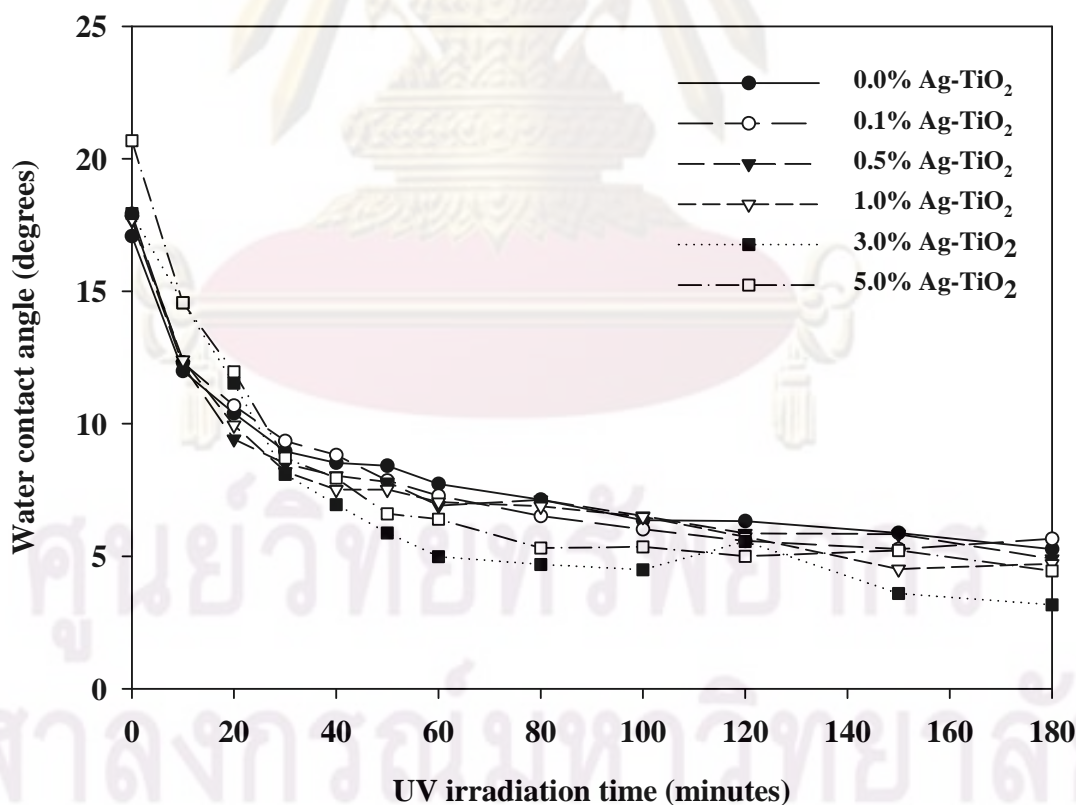

Figure 4.8 Change in contact angle of water droplet on the surface of various Ag-TiO₂ thin films.

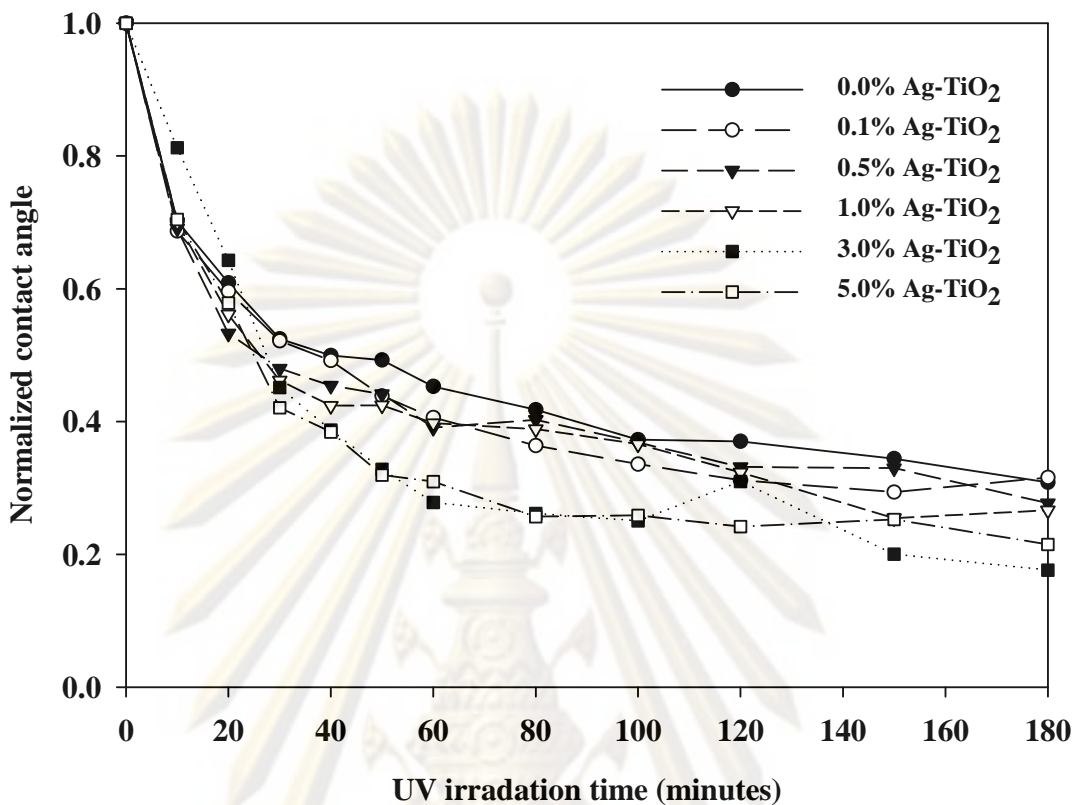

Figure 4.9 Change in normalized contact angle of water droplet on the surface of various Ag-TiO₂ thin films.

The role of silver species to the beneficial for hydrophilicity can be described as follow. After TiO₂ film was being irradiated, electrons and holes were generated as in Equation 2.4. The photo-generated electrons and holes will diffuse to the TiO₂ surface to created the surface oxygen vacancies (defective sites), according to mechanism of photo-induced hydrophilicity as seen in Equation 2.8 and 2.9 or undergo to recombine as in Equation 2.5. For Ag-TiO₂ films, photo-generated electrons were captured by Ag species and subsequently transferred to O₂ adsorbed on the surface to form O₂⁻ (Sakthivel et al., 2004 and Yang et al., 2008) as seen in Equation 4.1 and 4.2. Thus, the recombination of photo-generated electrons and holes in Equation 2.5 were effectively inhibited. Therefore, the separation of photo-generated electron-hole pairs increases the ability of holes transferring to TiO₂ surface and created more surface oxygen vacancies, which brought about higher hydrophilic properties of Ag-TiO₂ films. This result agreed with the result from PL spectra.

However, according to the results from PL spectra, the slowest recombination rate was found in TiO₂ films that contained 5.0 mol% silver (see Figure 4.6), but the changes in normalized contact angle of 5.0% Ag-TiO₂ film was almost identical to 3.0% Ag-TiO₂ film. This was attributed to, at 5.0 mol% of silver loading, the excessive amount of silver species on TiO₂ surface might be prevent the spreading of water droplets on film surface.

4.1.10 The sustainability of hydrophilicity of Ag-TiO₂ films after removal of UV irradiation

In order to assess the sustainability of hydrophilic property of Ag-TiO₂ film, the films were placed in a dark place with no exposure to light. As seen in Figure 4.10, the Ag-TiO₂ thin films that was able to retain the hydrophilic properties for the longest time was the films that contained 3.0-5.0 mol% silver. These observations suggested that the Ag-TiO₂ films that were able to retain the hydrophilicity for the longest time appeared to be the films that possessed the best hydrophilic property (i.e., 3-5 mol% Ag) to begin with.

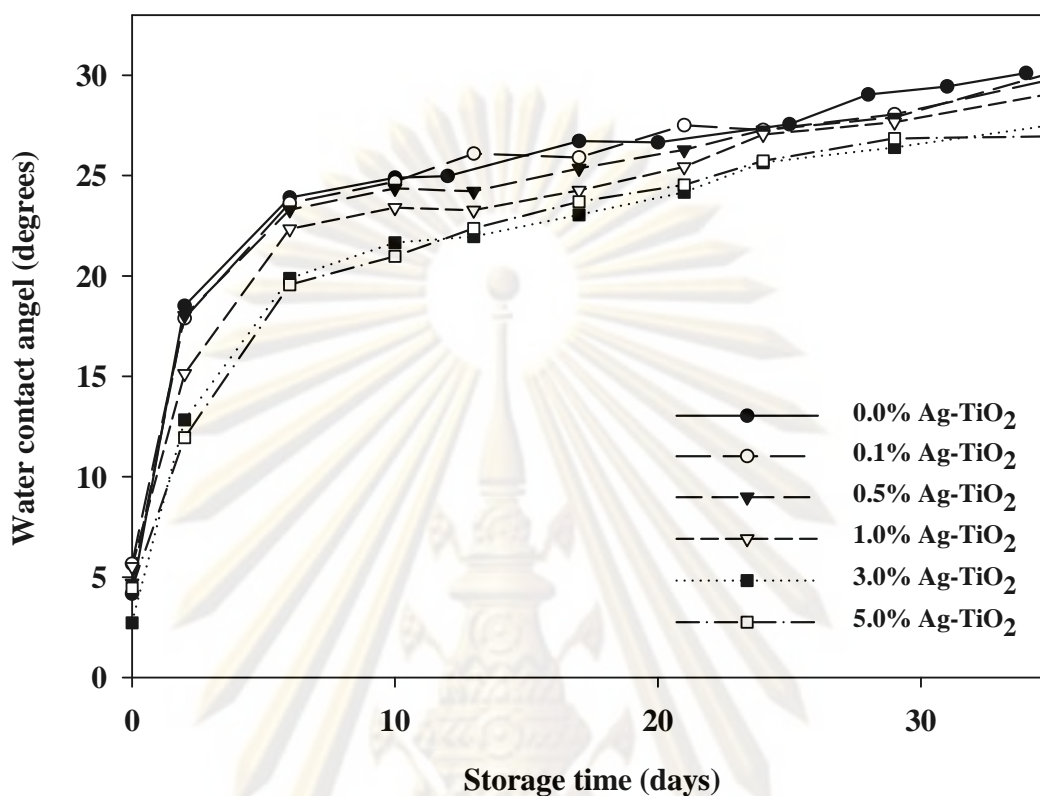

Figure 4.10 Change in contact angle of water droplet on the surface of various Ag-TiO₂ films in the absence of UV irradiation.

4.2 Effect of tungsten loading to TiO₂ thin films

4.2.1 Phase structures of W-TiO₂

The bulk crystalline phases of W-TiO₂ samples were investigated using X-ray diffractometer (XRD). In Figure 4.11 presents XRD patterns of W-TiO₂ powder after calcined at 350 °C under stagnant air for 2 hours. The amounts of tungsten loading were 0.1, 0.5, 1.0, and 1.5 mol% respectively. The major phase structure of TiO₂ was anatase, which were observed at 2θ of about 25.3° (101), 37.9° (004), 47.9° (200), 54.0° (105), 62.8 (204), and 69.2° (116). Small amount of rutile phase was observed at 2θ of about 27.3° (110) and 33.6° (101). The weak peak at 2θ of about 30° was assigned to brookite (121) phase which was a transitional phase from anatase to rutile in the healing processes (Shen et al., 2008). After tungsten

loading, the major phase structure of TiO_2 slightly changed. As seen at the diffraction peak of rutile phase at 2θ of 27.3° and 33.6° , their gradually disappeared when increased tungsten loading. This indicates that, tungsten species hindered the phase transformation of anatase to rutile during calcination process. This result agrees with the reports of Li and coworkers (2001) and Song and coworkers (2006). Furthermore, no diffraction peak corresponding to tungsten oxide were detected in any samples, this may be due to low amount of tungsten species or uniformly dispersed on TiO_2 surface.

Average crystallite size of anatase was calculated from the strongest peak of XRD patterns at 2θ about 25.3° (101) using Scherrer's formula. The results were listed in Table 4.6. The crystallite sizes of anatase TiO_2 decreased with increasing of tungsten loading, which corresponding with the broad of the diffraction peak. This indicated that tungsten species affect on the grain growth of anatase.

4.2.2 Oxidation state of tungsten in W-TiO₂

Figure 4.10 shows W 4f XPS spectra of W-TiO₂ that contained 1.5 mol% W. It was observed that, W 4f showed the broad peak, which was resulted by the overlap from two peaks spin-orbital splitting photoelectron of W 4f_{5/2} and W 4f_{7/2}. As seen in Figure 4.12, after W 4f peak was deconvoluted, two components of tungsten species were revealed at binding energy of 35.2 eV and 36.8 eV respectively. These were assigned to W^{4+} and W_xO_y (mixed valance of W^{6+} and W^{5+}). Therefore, it was clearly indicated that, W^{4+} , W^{5+} , and W^{6+} were existence in form of WO_2 , WO_3 , and W_xO_y (Song et al. 2006).

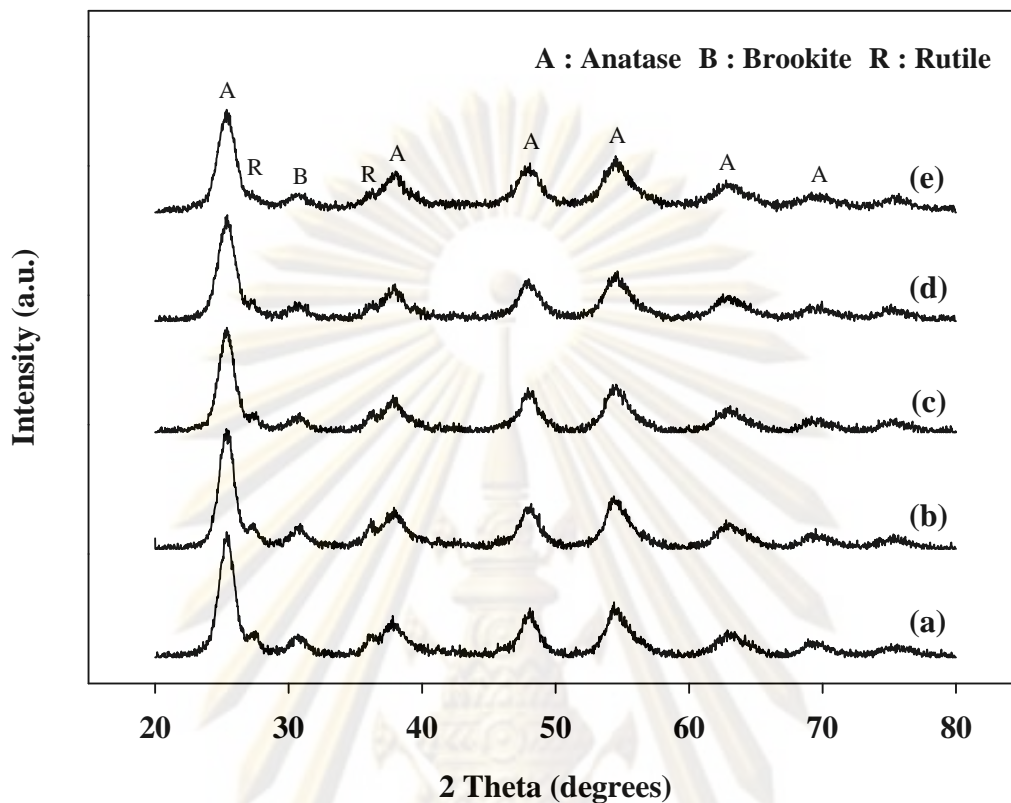

Figure 4.11 X-ray diffraction patterns of W-TiO₂ at various amount of tungsten loading when (a) 0.0 mol%, (b) 0.1 mol%, (c) 0.5 mol%, (d) 1.0 mol%, and (e) 1.5 mol% W.

0.5	6.3
1.0	5.5
1.5	5.4

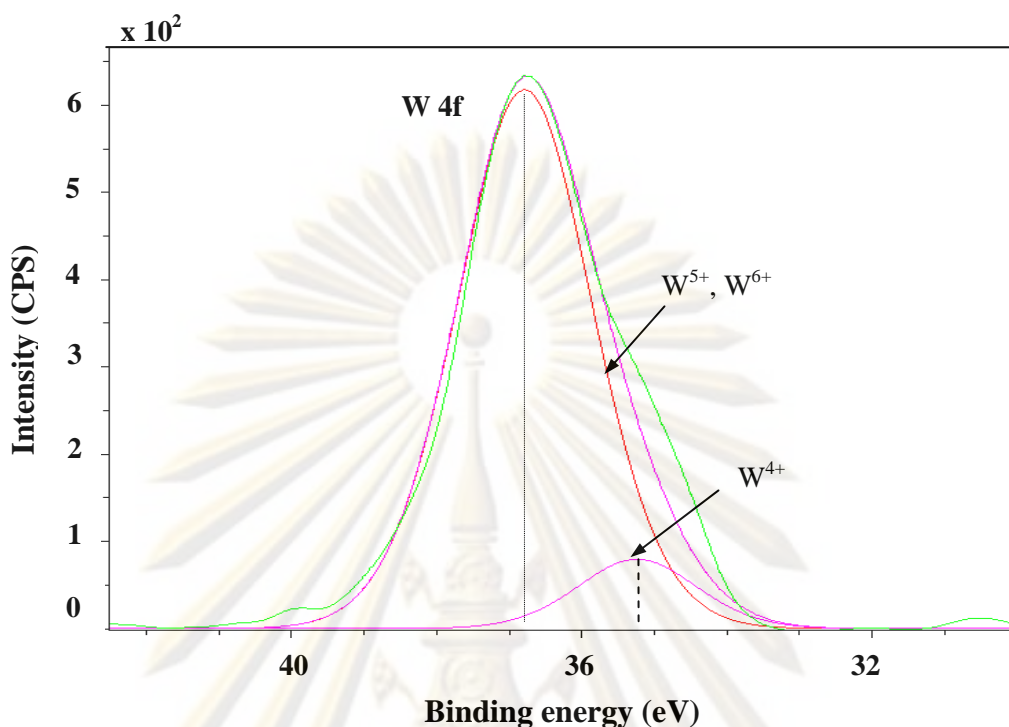

Figure 4.12 W 4f XPS spectra of W-TiO₂ that contained 1.5 mol% W.

4.2.3 Tungsten content in W-TiO₂

The amount of tungsten contents in W-TiO₂ sample was determined using inductively coupled-plasma optical emission spectroscopy (ICP-OES) and the results are shown in Table 4.7. As seen in Table 4.7, the real mole percentages of tungsten were found in W-TiO₂ was higher than that the expected values only slightly.

4.2.4 Specific surface area of W-TiO₂

The most common procedure for determining surface area of a solid is based on adsorption and condensation of nitrogen at liquid nitrogen temperature using static vacuum procedure. This method is also called BET (Brunauer Emmett Teller) method. Specific surface areas of W-TiO₂ with various amount of tungsten loading were listed in Table 4.8. The loading of tungsten have a significant effect on the specific surface area, which surface area increased with increasing the amount of tungsten loading, this was due to decreasing of crystallite size of TiO₂ (see Table 4.8).

1.5	108.5

4.2.5 Surface morphology of W-TiO₂ thin films

AFM was used to characterize the morphology and uniformity of surface. Figure 4.13 shows AFM images of W-TiO₂ thin film at various amount of tungsten loading. It was observed that, the surface topography of the films at various tungsten loading were obviously different. With increased tungsten loading, the smaller grain size was observed. This was suggested that, introducing of tungsten into TiO₂ suppressed the grain growth of TiO₂. Moreover, the average roughness of the W-TiO₂ film surface decreased with increasing the amount of tungsten loading from about 7.8 to 2.4 nm (see Table 4.9).

Figure 4.13 AFM images of W-TiO₂ film surface that contained (a) 0.0 mol%, (b) 0.1 mol%, (c) 0.5 mol%, (d) 1.0 mol%, and (f) 1.5 mol% W.

0.0	7.796
0.1	7.801
0.5	4.987
1.0	4.121
1.5	2.419

4.2.6 Light absorption characteristic of W-TiO₂ thin films

Figure 4.14 show UV-Vis absorption spectra of W-TiO₂ films deposited on glass surface in wavelength range of 300-700 nm. All films showed transmittance of light over 80 % entire visible region. The fast decreased in transmittance below 380 nm is due to absorption of light, which was caused by the excitation of electrons from the valance band to conduction of TiO₂ (Yu et al., 2002). When increased tungsten loading, the absorption edge of W-TiO₂ films shifted toward longer wavelength (red-shifted), this indicated that decreasing in band gap energy. To calculate the band gap energy of W-TiO₂ film, the graph of $(-2.303h\nu \log T)^{1/2}$ versus $h\nu$ was plotted and extrapolated in a linear part leading to the band gap energy (see in APPENDIX D). It was found that the band gap energies of TiO₂ and TiO₂ that contained tungsten of 0.1, 0.5, 1.0, and 1.5 mol% were 3.24, 3.18, 3.17, 3.17, and 3.16 respectively.

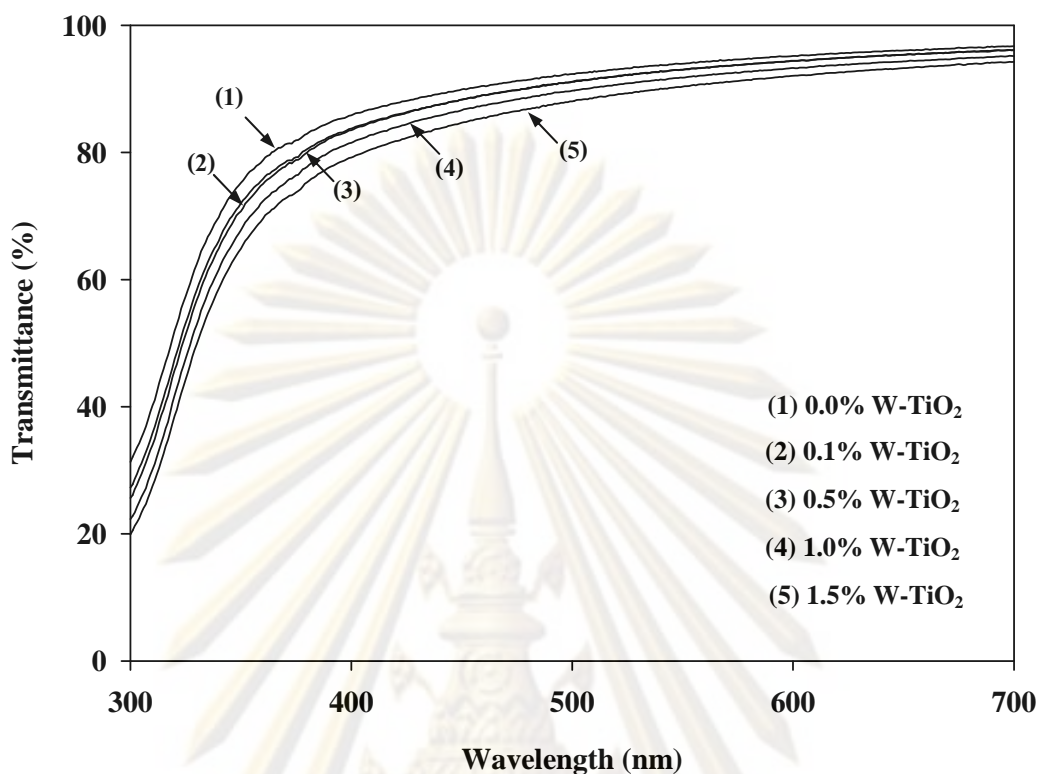

Figure 4.14 UV-Vis spectra of W-TiO₂ thin films deposited on glass surface.

4.2.7 Surface acidity of W-TiO₂

Temperature-programmed desorption (TPD) of probe molecules like ammonia and pyridine is a popular method for determining the acidity of solid catalysts as well as acid strength sites (Yang et al, 2005). In this investigation, the acidity measurement was carried out using NH₃-TPD. In Figure 4.15 presents NH₃-TPD profiles of W-TiO₂ at various amount of tungsten loading. There was only one asymmetric broad peak on the NH₃-TPD profiles of all the samples, and the peak temperatures are ranged between 50 and 600 °C, indicating that the acid sites on surface were the weak and strong strength (Yang et al, 2005 and Yoon et al., 2007). The overall surface acidity of W-TiO₂ increased as the amount of increased (see Table 4.10). It is well known that tungsten trioxide has Lewis acid sites (Yang et al, 2005). Furthermore, Tian and coworkers (2008) reported that WO₃/TiO₂ catalysts would exhibit surface acidity issued from the presence of Lewis and Bronsted acidic sites related to W⁶⁺ species.

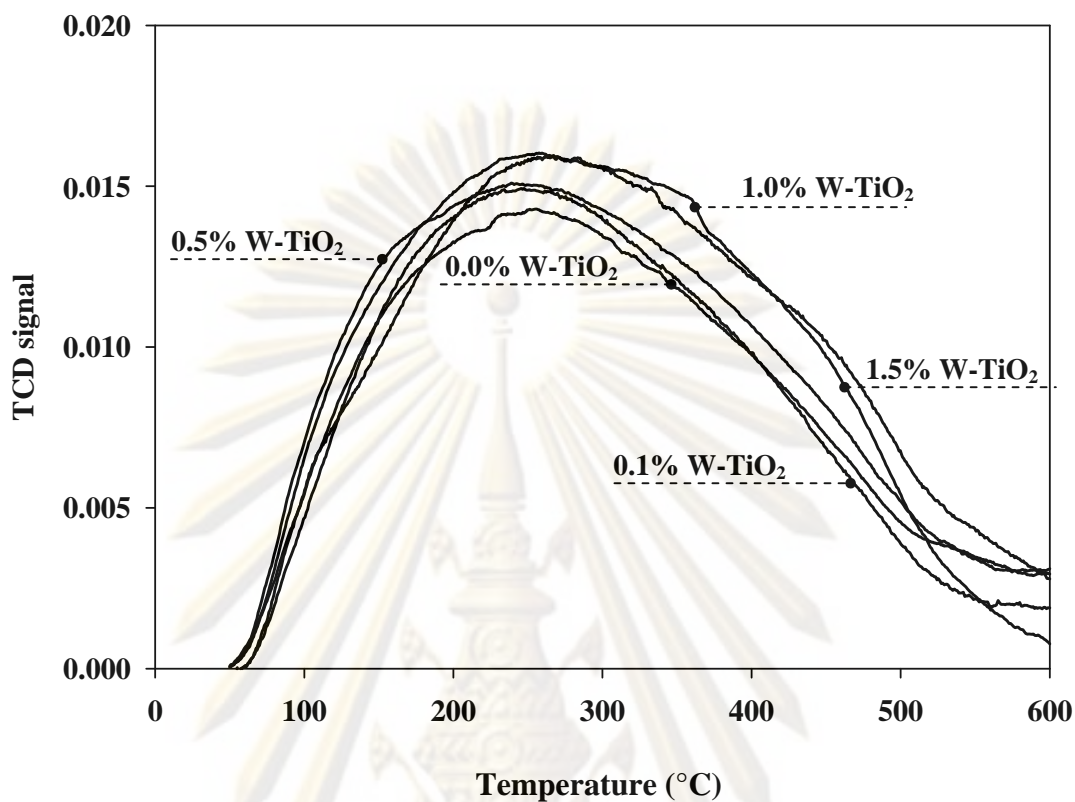

Figure 4.15 NH_3 -TPD profiles of W-TiO₂ at various amount of tungsten loading.

Table 4.10 Surface acidity of W-TiO₂ samples as determined from NH_3 -TPD profiles.

0.0	17.83
0.1	19.15
0.5	20.44
1.0	21.46
1.5	25.32

4.2.8 Photoluminescence spectra of W-TiO₂

The photoluminescence (PL) emission spectra have been widely used to investigate the efficiency of charge carrier trapping, immigration and transfer, and to understand the fate of electron-hole pairs in semiconductor particles (Li et al., 2001). Since PL emission mainly results from the recombination of photo-induced electrons and holes. The lower PL intensity indicates that the decreasing in recombination rate. In Figure 4.16 shows photoluminescence of W-TiO₂ at various amount of tungsten loading. It was observed that, PL spectra exhibited two emission peaks at the wavelength of about 420 and 485 nm. The former peak was due to free excitation emission of TiO₂ and the latter peak was due to the surface state such as Ti⁴⁺-OH (Nagaveni et al., 2004). With increased silver loading, PL intensity significantly decreased. This was described on the coupling of two kind semiconductors that (see Figure 4.17), the Schottky barrier at between two semiconductors can be formed because of their different Fermi level and electronic band structure (Linsebigler et al., 1995 and Liqiang et al., 2006). On the basis of the relevant band position of WO₃ and TiO₂, both the conduction and valence band of WO₃ have larger positive potentials than that TiO₂. After W-TiO₂ being irradiated, photo-generated electrons are transferred to the lower conduction band of WO₃, while the holes will accumulate in the valence band of TiO₂ and further transferred to surface. Moreover, the photo-generated holes are transferred to valence band of WO₃ to valence of TiO₂ (Li et al., 2001 and Chai et al., 2006). Therefore, the photo-generated electron-hole pairs were effectively separated rather than undergoing recombination. This reason caused the decreasing in PL intensity after loading of tungsten to TiO₂.

Figure 4.16 PL spectra of W-TiO₂ at various amount of tungsten loading.

Figure 4.17 Energy diagram at interfacial for W-TiO₂.

4.2.9 Photo-induced hydrophilicity of W-TiO₂ films

In figure 4.18 shows the change in water contact angle of W-TiO₂ films after UV irradiation for 3 hours. Before irradiation, all films had the initial contact angle about 18 degrees. When the films were being irradiated, the contact angle gradually decreased until the angle reached to a steady state value, called saturated contact angle about 5 degrees. For TiO₂ film, the time needed to reach a saturated contact angle approximately 120 minutes. When increased tungsten loading, the time needed to reach a saturated contact angle were shorter than that TiO₂. Especially for 1.0 and 1.5% W-TiO₂ films showed the shortest time to reach a saturated contact angle approximately 50 minutes. Therefore, TiO₂ films that contained 1.0-1.5 mol% W possessed the best hydrophilic properties (or the shortest time to reach a saturated contact angle).

According to the results from PL spectra, the slowest recombination rates were also found in TiO₂ films that contained 1.0 and 1.5 mol% W too (see Figure 4.16). Therefore, the separation of photo-generated electron-hole pairs increases the ability of holes transferring to TiO₂ surface and created more surface oxygen vacancies (defective sites), which brought about higher hydrophilic properties of W-TiO₂ films. In addition, the adsorption sites for anions and cations are charged surface groups resulting from the protonation–deprotonation equilibria of the surface hydroxyl groups (Paola et al., 2004). The acidic surface has a higher affinity for species with unpaired electrons (Tian et al., 2008). According results from NH₃-TPD profile, the total acid sites increased after tungsten loading (see Table 4.10). Therefore, more acid sites on W-TiO₂ surface can adsorb a greater amount of hydroxyl groups or water molecule, which is led to increase the hydrophilic property of TiO₂ surface.

Figure 4.18 Change in contact angle of water droplet on the surface of various W-TiO₂ films.

4.2.10 The sustainability of hydrophilicity of W-TiO₂ films after removal of UV irradiation

In order to assess the sustainability of hydrophilic property of W-TiO₂ film, the films were placed in a dark place with no exposure to light as seen in Figure 4.19, the W-TiO₂ thin films that was able to retain the hydrophilic properties for the longest time was the films that contained 1.0-1.5 mol% W. These observations suggested that the W-TiO₂ films that were able to retain the hydrophilicity for the longest time appeared to be the films that possessed the highest hydrophilic properties (i.e., 1.0-1.5 mol% W) to begin with.

Figure 4.19 Change in contact angle of water droplet on the surface of various W-TiO₂ films in the absence of UV irradiation.

4.3 Effect of copper loading to TiO₂ thin film

4.3.1 Phase structures of Cu-TiO₂

The bulk crystalline phase of Cu-TiO₂ samples were investigated using X-ray diffractometer (XRD). In Figure 4.20 presents XRD patterns of Cu-TiO₂ powder after calcined at 350 °C under stagnant air for 2 hours. The amounts of copper loading were 0.1, 0.5, 1.0, and 5.0 mol% respectively. The major phase structure of TiO₂ was anatase, which were observed at 2θ of about 25.3° (101), 37.9° (004), 47.9° (200), 54.0° (105, 211), 62.8 (204) and 69.2° (116). Small amount of rutile phase was observed at 2θ of about 27.3° (110) and 33.6° (101). The weak peak at 2θ of about 30° was assigned to brookite (121) phase, which was a transitional phase from anatase to rutile in the healing processes (Shen et al., 2008). After copper loading, the major

phase structure and crystallinity of TiO₂ still unchanged, indicated that loading of copper did not affect to the crystallization of TiO₂. Furthermore, no diffraction peak corresponding to copper oxide were detected in any samples, this may be due to the amount of copper species very low or uniformly dispersed on TiO₂ surface.

Average crystallite size of anatase was calculated from the strongest peak of XRD patterns at 2θ about 25.3° (101) using Scherrer's formula. The results were listed in Table 4.11. The loading of copper to TiO₂ did not have an effect on the average crystallite size of anatase.

4.3.2 Oxidation state of copper in Cu-TiO₂

Figure 4.21 shows XPS spectra of Cu 2p for Cu-TiO₂ that contained 15 mol% Cu. A major difference between Cu⁺ and Cu²⁺ is the prominent satellite structure on the high binding energy side of the copper core line for Cu²⁺ species. These satellites have been attributed to shake-up transition by ligand-to-metal 3d charge transfer. This charge transfer cannot occur in Cu⁺ (Colon et al., 2006). As seen in Figure 4.21, the Cu 2p_{3/2} and Cu 2p_{1/2} spin-orbital splitting photoelectron were located at binding energies of 933.6 eV and 953.3 eV and together with the characteristic shake-up feature at binding energy of 942.3 eV and 961.9 eV respectively. This was clearly indicated that, the existence of copper species were form in Cu²⁺ (CuO) (Colon et al., 2006 and Xu et al. 2008).

Figure 4.20 X-ray diffraction patterns of Cu-TiO₂ with various copper loading when (a) 0.0 mol%, (b) 0.1 mol%, (c) 0.5 mol%, (d) 1.0 mol%, and (e) 5.0 mol% Cu.

4.2.3 Copper content in Cu-TiO₂

The amount of tungsten contents in Cu-TiO₂ sample was determined using inductively coupled-plasma optical emission spectroscopy (ICP-OES) and the results are shown in Table 4.12. As seen in Table 4.12, the real mole percentages of copper were found in Cu-TiO₂ was higher than that the expected values only slightly.

Table 4.12 The amount of copper contents in Cu-TiO₂.

Amount of copper loading (mol%)	Amount of copper from ICP (mol%)
0.1	0.134
0.5	0.678
1.0	1.295
5.0	5.891

4.3.4 Specific surface area of Cu-TiO₂

The most common procedure for determining surface area of a solid is based on adsorption and condensation of nitrogen at liquid nitrogen temperature using static vacuum procedure. This method is also called BET (Brunauer Emmett Teller) method. Specific surface areas of Cu-TiO₂ at various amount of copper loading were listed in Table 4.13. Specific surface area of TiO₂ was 104.4 m²/g. After copper loading, surface areas were decreased. However, the amount of copper loading did not have a significant effect on the specific surface area, which was appeared in the range of 94.4-104.4 m²/g.

Table 4.13 Specific surface area of Cu-TiO₂ at various amount of copper loading.

Amount of copper loading (mol%)	Specific surface area (m ² /g)
0.0	104.4
0.1	97.9.
0.5	95.9
1.0	94.4
5.0	96.9

4.3.5 Surface morphology of Cu-TiO₂ thin films

AFM was used to characterize the morphology and uniformity of surface. Figure 4.22 shows AFM images of Cu-TiO₂ film surface that contained various amount of copper. It was observed that, all films had a uniform surface. The loading of copper into TiO₂ did not have a significant effect on the grain size of TiO₂. Analysis of AFM images revealed that the average roughness of the Cu-TiO₂ films surface appeared in the range of 1.663-2.534 nm (see Table 4.14).

Figure 4.22 AFM images of Cu-TiO₂ film surface that contained (a) 0.0 mol% (b) 0.1 mol% (c) 0.5 mol% (d) 1.0 mol% and (f) 5.0 mol% Cu.

4.3.6 Light absorption characteristic of Cu-TiO₂ thin films

Figure 4.23 shows UV-Vis absorption spectra of Cu-TiO₂ films deposited on glass surface in wavelength range of 300-700 nm. All films showed transmittance of light over 80 % in visible region. The fast decreased in transmittance below 380 nm was due to absorption of light, which was caused by the excitation of electrons from the valance band to conduction of TiO₂ (Yu et al., 2002). When increased copper loading, the absorption edge of Cu-TiO₂ films were shifted toward longer wavelength (red-shifted), this indicated that decreasing in band gap energy. To calculate the band gap energy of Cu-TiO₂ film, the graph of $(-2.303h\nu\log T)^{1/2}$ versus $h\nu$ was plotted and extrapolated in a linear part leading to the band gap energy (see in APPENDIX D). It was found that the band gap energies of TiO₂ and TiO₂ that contained copper of 0.1, 0.5, 1.0, and 5.0 mol% were 3.24, 3.22, 3.24, 3.21, and 3.18 respectively.

Figure 4.23 UV-Vis spectra of Cu-TiO₂ thin films deposited on glass surface.

4.3.7 Surface acidity of Cu-TiO₂

Temperature-programmed desorption (TPD) of probe molecules like ammonia and pyridine is a popular method for determining the acidity of solid catalysts as well as acid strength sites (Yang et al, 2005). In this investigation, the acidity measurement was carried out using NH₃-TPD. In Figure 4.24 presents NH₃-TPD profiles of Cu-TiO₂ with various amount of copper loading. There was only one asymmetric broad peak on the NH₃-TPD profiles of all the samples, and the peak temperatures are ranged between 50 and 600 °C, indicating that the acid sites on surface were the weak and strong strength (Yang et al, 2005 and Yoon et al., 2007). The total acid sites of Cu-TiO₂ were listed in Table 4.15, which loading of copper did not have a significant effect on the overall surface acidity of Cu-TiO₂.

Amount of copper loading (mol%)	Total acid site (mmol NH_3/g)
0.0	19.87
0.1	22.57
0.5	20.63
1.0	20.38
1.5	24.35

4.3.8 Photoluminescence spectra of Cu-TiO₂

The photoluminescence (PL) emission spectra have been widely used to investigate the efficiency of charge carrier trapping, immigration and transfer, and to understand the fate of electron-hole pairs in semiconductor particles (Li et al., 2001). Since PL emission mainly results from the recombination of photo-induced electrons and holes. The lower PL intensity indicates that the decreasing in recombination rate. In Figure 4.25 shows PL of Cu-TiO₂ at various amount of copper loading. It was observed that, PL spectra exhibit two emission peaks at the wavelength of about 420 and 485 nm. The former peak was due to free excitation emission of TiO₂ and the latter peak was due to the surface state such as Ti⁴⁺-OH (Nagaveni et al., 2004). As seen Figure 4.25, the PL intensity decreased with increased the loading of copper. This is mainly due to electronic capture of Cu²⁺. Cu²⁺ easily captures photo-induced electrons to become Cu⁺ which stable chemical state with a full-filled outer electronic ($1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10}$) (liqiang et al., 2006 and Xu et al. 2008). This results also agree with the results of Choi et al., 2007, which reported that CuO in Cu/TiO₂ before the reaction was populated to be reduced during the methanol/water photodecomposition. Therefore, the photo-generated electron-hole pairs were effectively separated rather than undergoing recombination. This reason caused the decreasing in PL intensity after loading of copper to TiO₂.

4.3.9 Photo-induced hydrophilicity of Cu-TiO₂ films

In figure 4.27 shows the changes in water contact angle of Cu-TiO₂ film after UV irradiation for 3 hours. Before irradiation, the films had the initial contact angle about 23-25 degrees. When the films being were irradiated, the contact angle gradually decreased until the angle reached to a steady state value, called saturated contact angle. For TiO₂ film, the time needed to reach a saturated contact angle about 5 degrees approximately 120 minutes. When increased copper loading, the saturated contact angle of all Cu-TiO₂ films not reach to 5 degrees as to TiO₂ films within 180 minutes. So, Cu-TiO₂ films possessed worse hydrophilic properties than TiO₂ film did.

Figure 4.25 PL spectra of Cu-TiO₂ at various amount of copper loading.

Figure 4.26 Photoreduction of Cu (II) at interfacial of Cu-TiO₂.

Figure 4.27 Change in contact angle of water droplet on the surface of various Cu-TiO₂ films.

According to the above discussion in section 4.3.7, Cu²⁺ (CuO) in all Cu-TiO₂ films were photo-reduced by photo-induced electrons to higher stable form of Cu⁺ (Cu₂O). Thus, the ability of Cu²⁺ to capture photo-induced electrons is higher than that to produce surface oxygen vacancies on TiO₂ surface according to the mechanism of photo-induced hydrophilicity. Therefore, the lower surface oxygen vacancies were created, which brought about lower hydrophilic properties of Cu-TiO₂ films. Furthermore, CuO itself does not exhibit hydrophilicity (Miyayuchi, 2002). Thus, with increasing content of copper loading, the hydrophilicity of Cu-TiO₂ films decreased comparatively to TiO₂ film.

4.3.10 The sustainability of hydrophilicity of Cu-TiO₂ films after removal of UV irradiation

In order to assess the sustainability of hydrophilic property of Cu-TiO₂ film, the films were placed in a dark place with no exposure to light. As seen in Figure 4.28, the ability to retain the hydrophilic property of Cu-TiO₂ films after removal of UV irradiation was worse than that of TiO₂ film. These findings agreed with observation previously mentioned that the film with better hydrophilic property could retain the hydrophilic property longer.

Figure 4.28 Change in contact angle of water droplet on the surface of various Cu-TiO₂ films in the absence of UV irradiation.

4.4 Effect of Molybdenum loading to TiO₂ thin films

4.4.1 Phase structures of Mo-TiO₂

The bulk crystalline phases of Mo-TiO₂ samples were investigated using X-ray diffractometer (XRD). In Figure 4.29 presents XRD patterns of Mo-TiO₂ powder after calcined at 350 °C under stagnant air for 2 hours. The amounts of molybdenum loading were 0.1, 0.3, 0.5, 0.7, and 1.0 mol% respectively. The major phase structure of TiO₂ was anatase, which were observed at 2θ of about 25.3° (101), 37.9° (004), 47.9° (200), 54.0° (105), 62.8° (204), and 69.2° (116). Small amount of rutile phase was observed at 2θ of about 27.3° (110) and 33.6° (101). The weak peak at 2θ of about 30° was assigned to brookite (121) phase which was a transitional phase from anatase to rutile in the healing processes (Shen et al., 2008). After molybdenum loading, the major phase structure and crystallinity of TiO₂ still unchanged, indicating that loading of molybdenum did not affect to the crystallization of TiO₂. Furthermore, no diffraction peak corresponding to molybdenum oxide was detected in any samples. This may be due to the amount of molybdenum species very low or uniformly dispersed on TiO₂ surface.

Average crystallite size of anatase was calculated from the strongest peak of XRD patterns at 2θ about 25.3° (101) using Scherrer's formula. The results were listed in Table 4.16. Loading of molybdenum to TiO₂ did not have the effect on the average crystallite size of anatase.

4.4.2 Oxidation state of molybdenum in Mo-TiO₂

Figure 4.30 shows Mo 3p XPS spectra of Mo-TiO₂ that contained 10 mol% Mo. It was observed that, the Mo 3p spectra consisted of two peaks spin-orbital splitting photoelectron (Mo 3p_{3/2} and Mo 3p_{1/2}), which located at the binding energies of 398.0 and 415.6 eV respectively. These were assigned to Mo⁶⁺ (Zhang et al., 2008). Therefore, it was clearly indicated that, Mo⁶⁺ was existence in form of MoO₃.

Figure 4.29 X-ray diffraction patterns of Mo-TiO₂ with various Mo loading when (a) 0.0 mol%, (b) 0.1 mol%, (c) 0.3 mol%, (d) 0.5 mol%, (e) 0.7 mol%, and (f) 1.0 mol% Mo.

4.4.4 Specific surface area of Mo-TiO₂

The most common procedure for determining surface area of a solid is based on adsorption and condensation of nitrogen at liquid nitrogen temperature using static vacuum procedure. This method is also called BET (Brunauer Emmett Teller) method. Specific surface areas of Mo-TiO₂ at various amount of molybdenum loading were listed in Table 4.18. Specific surface area of TiO₂ was 103.8 m²/g. After molybdenum loading, surface areas were decreased. However, the amount of molybdenum loading did not have a significant effect on the specific surface area, which was appeared in the range of 80.8-89.4 m²/g.

4.4.5 Surface morphology of Mo-TiO₂ thin films

AFM was used to characterize the morphology and uniformity of surface. Figure 4.31 shows AFM images of Mo-TiO₂ film surface that contained various amount of molybdenum. It was observed that, that loading of molybdenum into TiO₂ did not have a significant effect on the grain size of TiO₂. Analysis of AFM images suggested that average roughness of the Mo-TiO₂ films surface appeared in the range of 1.693-2.960 nm (see Table 4.19).

4.4.7 Surface acidity of Mo-TiO₂

Temperature-programmed desorption (TPD) of probe molecules like ammonia and pyridine is a popular method for determining the acidity of solid catalysts as well as acid strength sites (Yang et al, 2005). In this investigation, the acidity measurement was carried out using NH₃-TPD. In Figure 4.33 presents NH₃-TPD profiles of Mo-TiO₂ with various amount of molybdenum loading. There was only one asymmetric broad peak on the NH₃-TPD profiles of all the samples, and the peak temperatures are ranged between 50 and 600 °C, indicating that the acid sites of the samples were weak and strong strength (Yang et al, 2005 and Yoon et al., 2007). The total acid sites of Mo-TiO₂ were listed in Table 4.20. After molybdenum loading, total acid site decreased. However, the amount of molybdenum loading did not have a significant effect on the surface acidity of Mo-TiO₂.

4.4.8 Photoluminescence spectra of Mo-TiO₂

The photoluminescence (PL) emission spectra have been widely used to investigate the efficiency of charge carrier trapping, immigration and transfer, and to understand the fate of electron-hole pairs in semiconductor particles (Li et al., 2001). The PL emission mainly results from the recombination of photo-induced electrons and holes. The lower PL intensity indicates that the decreasing in recombination rate. In Figure 4.34 shows PL of Mo-TiO₂ at various amount of Mo loading. It was observed that, PL spectra exhibited two emission peaks at the wavelength of about 420 and 485 nm. The former peak was due to free excitation emission of TiO₂ and the latter peak was due to the surface state such as Ti⁴⁺-OH (Nagaveni et al., 2004). As seen Figure 4.34, the photoluminescence intensity decreased with increasing the loading of molybdenum. This was attributed to molybdenum species can act as traps for photo-induced electrons. Therefore, the photo-generated electron-hole pairs were effectively separated rather than undergoing recombination. This reason caused the decreasing in PL intensity after loading of molybdenum to TiO₂.

Figure 4.34 PL spectra of Mo-TiO₂ at various amount of molybdenum loading.

4.4.9 Photo-induced hydrophilicity of Mo-TiO₂ films

In figure 4.35 shows the changes in water contact angle of Mo-TiO₂ film after UV irradiation for 3 hours. Before irradiation, the films had the initial contact angle about 18-21 degrees. When the films being were irradiated, the contact angle gradually decreased until the angle reached to a steady state value, called saturated contact angle. For TiO₂ film, the time needed to reach a saturated contact angle about 5 degrees approximately 120 minutes. When increased Mo loading, the saturated contact angle of all Mo-TiO₂ films about 10 degrees, which higher than that TiO₂ films. So Mo-TiO₂ film possessed worse hydrophilic properties than TiO₂ film did. This was attributed to the ability of molybdenum to captures photo-induced electrons is higher than that to produces surface oxygen vacancies on TiO₂ surface according to the mechanism of photo-induced hydrophilicity. Therefore, the lower surface oxygen vacancies were created, which brought about lower hydrophilic

properties of Mo-TiO₂ films. Furthermore, MoO₃ itself does not exhibit hydrophilicity (Miyayuchi, 2002). Thus, with increasing content of molybdenum loading, the hydrophilicity of Mo-TiO₂ films decreased comparatively to TiO₂ film.

4.1.10 The sustainability of hydrophilicity of the films after removal of UV irradiation

In order to assess the sustainability of hydrophilic property of Mo-TiO₂ film, the films were placed in a dark place with no exposure to light. As seen in Figure 4.36, the ability to retain the hydrophilic property of Mo-TiO₂ films after removal of UV irradiation was worse than that of TiO₂ film. These findings agreed with observation previously mentioned that the film with better hydrophilic property could retain the hydrophilic property longer.

Figure 4.35 Change in contact angle of water droplet on the surface of various Mo-TiO₂ films.

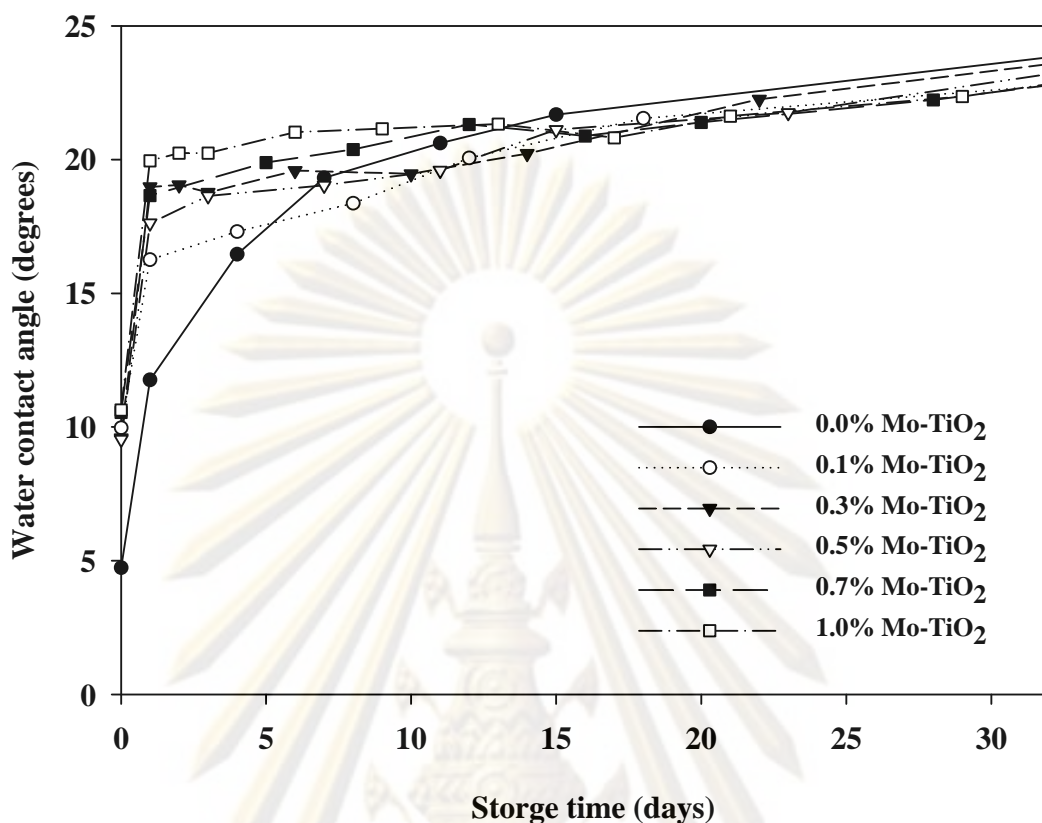

Figure 4.36 Change in contact angle of water droplet on the surface of various Mo-TiO₂ films in the absence of UV irradiation.

4.5 Reduction behavior of metal loaded-TiO₂

According to the result of photo-induced hydrophilicity, adding of silver or tungsten enhanced the hydrophilic property of the films but neither adding of copper or molybdenum did not enhance the hydrophilic property. In order to investigate the overall conclusion of metal loading to the hydrophilic property of the film that may be correlated to the reduction behavior of metal species. Therefore, temperature programmed-reduction (TPR) was performed and the result of the TPR profiles of Ag-, W-, Cu-, and Mo-TiO₂ were shown in Figure 4.37. As seen in the TPR profile of Ag-TiO₂, the reduction peak was observed at the temperature around 100 °C which was due to the reduction of dispersed Ag⁺ species (Nanba et al., 2008). For W-TiO₂ sample, only one reduction peak was observed at the temperature around 520 °C. This peak was due to the reduction of W⁶⁺ to W⁵⁺ and then to W⁴⁺ (Engweiler et al. 1996 and Benitez et al., 2002). Moreover, the tail of the TPR profile does not reach to the

base line at the end of experiment. This was due to further reduction to W^0 at the temperature higher than 800 °C. For Cu-TiO₂ sample, two reduction peaks were observed at the temperature around 260 °C and 406 °C. The former peak was due to the reduction of highly dispersed CuO species interacting with TiO₂ and the latter peak was due to the reduction from bulk CuO crystallites (Xiaoyuan et al, 2004 and Luo et al., 2005). For Mo-TiO₂ sample, two steps of reduction were observed at the temperatures around 445 °C and 776 °C. This two reduction peaks were due to the reduction of Mo⁶⁺ in both tetrahedral and octahedral coordinate to Mo⁴⁺ (Arnoldy et al., 1984 and Chary et al., 2001). Moreover, the reduction peak of Mo⁴⁺ to Mo⁰ will be appeared at the temperature higher than 800 °C, which cannot observe in this experiment condition. According to the result from the TPR profile and photo-induced hydrophilicity, if the reduction behavior (easy to reduce) has been correlate with the hydrophilic property, the reduction should be in the order of Cu-TiO₂~Mo-TiO₂> Ag-TiO₂~W-TiO₂. However, as seen in Figure 4.37, the reduction was in the order of Ag-TiO₂>Cu-TiO₂>Mo-TiO₂>W-TiO₂ respectively. Thus, the reduction behavior of metal species did not correlated to the hydrophilic property of the film.

Figure 4.37 TPR profiles of metal loaded-TiO₂ that contained 1.0 mol% metal.

CHAPTER V

CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

In this study, to investigate the effect of metal (Ag, W, Cu, or Mo) loading to TiO₂ on photo-induced hydrophilicity of TiO₂ thin films and their abilities to retain hydrophilicity after removal of UV irradiation. The overall conclusions are the following;

5.1.1 TiO₂ film containing 3.0-5.0 mol% silver or 1.0-1.5 mol% tungsten possessed the best hydrophilic properties because the recombination of photo-generated electrons and holes were effectively inhibited, which agreed with the results from photoluminescence spectra.

5.1.2 Adding of copper (0.1-5.0 mol%) and molybdenum (0.1-1.0 mol%) to TiO₂ films did not improve the hydrophilicity of the thin films because the photo-generated electrons were captured by their metal oxide instead of creating surface oxygen vacancies on TiO₂ surface. Furthermore, neither CuO nor MoO₃ possessed hydrophilicity. An increase in the content of copper or molybdenum in TiO₂ worsened the hydrophilic property of the film.

5.1.3 The better the hydrophilic property of the thin film, the longer the ability of the thin film to retain its hydrophilicity after removal UV irradiation.

5.2 Recommendations

The following recommendations for future studies are proposed.

5.2.1 The film sample was used in another application such as decomposition the hydrocarbon compound, treats the water and air pollution.

5.2.2 Other preparation for prepare TiO₂ thin film should be tried.

APPENDIX A

CALCULATION OF THE CRYSTALLITE SIZE

Calculation of the crystallite size

The crystallite size was calculated from the width at half-height of the diffraction peak of XRD pattern using the Debye-Scherrer formula according to Equation A.1;

$$D = \frac{K\lambda}{\beta \cos \theta} \quad (\text{A.1})$$

where D is crystallite size (Å)
K is crystallite-shape factor (0.9)
 λ is X-ray wavelength (1.5418 Å for Cu K α)
 θ is diffraction angle (degree)
 β is X-ray diffraction broadening (radian)

The X-ray diffraction broadening (β) is the pure width of a powder diffraction, free of all broadening due to the experimental equipment. Standard α -alumina is used to observe the instrumental broadening since its crystallite size is larger than 2000 Å. The X-ray diffraction broadening (β) can be obtained by using Warren's formula;

$$\beta^2 = B_M^2 - B_S^2 \quad (\text{A.2})$$

$$\beta = \sqrt{B_M^2 - B_S^2}$$

where B_M is the measured peak width in radians at half peak height
 B_S is the corresponding width of a standard material

Example: Calculation of the crystallite size of titanium dioxide.

In Figure A.1, the half-height width of 101 diffraction peak

$$= 1.80813^\circ$$

$$= 0.03156 \text{ radian}$$

The corresponding half-height width of peak = 0.004 radian

$$\text{The pure width} = \sqrt{B_M^2 - B_S^2}$$

$$= \sqrt{0.03156^2 - 0.004^2}$$

$$= 0.03132 \text{ radian}$$

$$\beta = 0.03132 \text{ radian}$$

$$2\theta = 25.28^\circ$$

$$\theta = 12.64^\circ$$

$$\lambda = 1.5418 \text{ \AA}$$

$$\text{The crystallite size} = \frac{0.9 \times 1.5418}{0.03132 \cos 12.64}$$

$$= 45.40 \text{ \AA}$$

$$= 4.5 \text{ nm}$$

Figure A.1 The 101 diffraction peak of TiO₂ for calculation of the crystallite size.

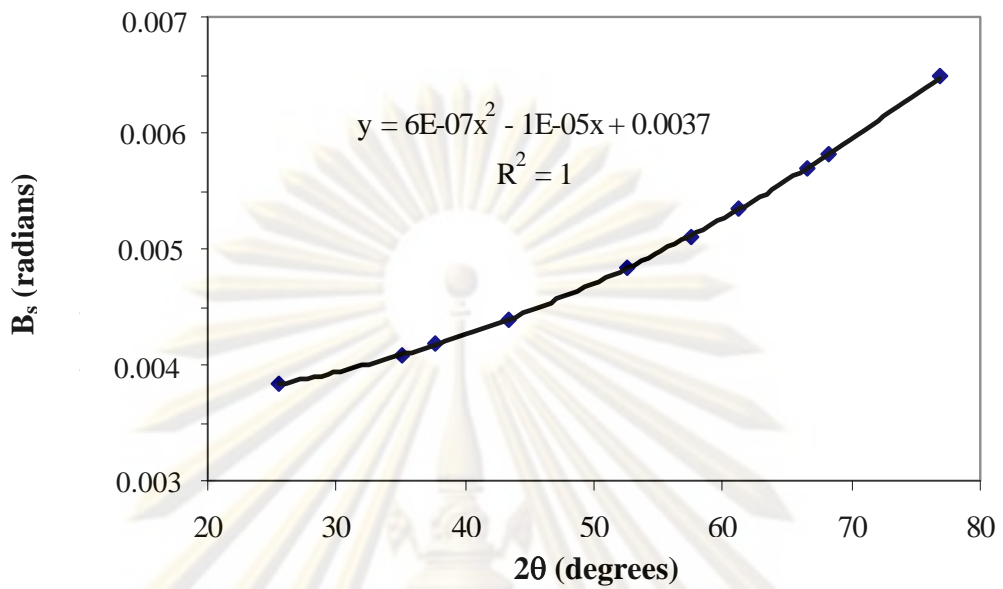

Figure A.2 The plot indicating the value of line broadening due to the equipment. The data were obtained by using α -alumina as standard.

APPENDIX B

DETERMINATION OF LATTICE PARAMETERS OF TITANIUM DIOXIDE

Interplanar spacing (d-spacing) can be calculated from the Bragg's law according to Equation B.1;

$$2d_{hkl} \sin \theta = n\lambda \quad (\text{B.1})$$

where d_{hkl} is the distance between crystal planes (Å)

θ is the diffraction angle (degree)

λ is X-ray wavelength (1.5418 Å for Cu K_{α})

a , b and c are lattice parameters (for anatase, $a = b \neq c$) (Å)

$(h \ k \ l)$ is Miller's index

So, at a fixed-wavelength (controlled by the XRD machine: target, filter, etc.) for a certain value of d-spacing (characteristic of samples). After obtaining the d-spacing of each plane, a-cell and c-cell of lattice parameter in tetragonal crystal system (see Figure B.1) can be calculated according to Equation B.2;

$$d_{hkl} = \frac{a}{[h^2 + k^2 + l^2(\frac{a^2}{c^2})]^{1/2}} \quad (\text{B.2})$$

ศูนย์วิจัยทรัพยากร

จุฬาลงกรณ์มหาวิทยาลัย

Figure B.1 Tetragonal crystal structure of titanium dioxide.

Example: Calculation the lattice parameter of titanium dioxide

To calculation the lattice parameter of anatase TiO_2 , we select the (101) and (200) plane for determine the d-spacing values. The steps for calculation as followed below;

1. From the diffraction patterns of 0.0% Ag- TiO_2 , the diffraction angle of anatase TiO_2 in (101) and (200) plans were 25.38° and 48.26° respectively. So, substitute in Equation (B.1);

$$d_{101} = \frac{(1)(1.5418)}{(2)[\sin(25.38/2)]} = 3.5093 \text{ \AA}$$

$$d_{200} = \frac{(1)(1.5418)}{(2)[\sin(48.26/2)]} = 1.8857 \text{ \AA}$$

2. The d-spacing of (200) plane is used to determine a-cell parameter;

$$a = (2)(d_{200}) = (2)(1.8857) = 3.7714 \text{ \AA}$$

3. The c-cell parameter can be determined from Equation (B.2);

$$\begin{aligned} c &= \left(-\frac{(d_{101})^2 (a)^2}{((d_{101})^2 - (a)^2)} \right)^{1/2} \\ &= \left(-\frac{(3.5093)^2 (3.7714)^2}{((3.5093)^2 - (3.7714)^2)} \right)^{1/2} \\ &= 9.5792 \text{ \AA} \end{aligned}$$

3. So, the crystal volume of TiO_2 can be calculated from;

$$\begin{aligned} \text{Crystal volume} &= (a)^2(c) \\ &= (3.7714)^2(9.5792) \\ &= 136.2530 \text{ \AA}^3 \end{aligned}$$

DATA AND CALCULATION OF ACID SITE

Table C.1 Reported total peak area from Micromeritics Chemisorb 2750

Sample	Weight (g)	Total peak area
0.0% Ag-TiO ₂	0.1026	5.2705
0.1% Ag-TiO ₂	0.1056	5.3526
0.5% Ag-TiO ₂	0.1001	5.1601
1.0% Ag-TiO ₂	0.1010	4.8433
3.0% Ag-TiO ₂	0.1011	4.5922
5.0% Ag-TiO ₂	0.1011	4.2448
0.0% W-TiO ₂	0.1025	3.9456
0.1% W-TiO ₂	0.1020	4.2178
0.5% W-TiO ₂	0.1011	4.4608
1.0% W-TiO ₂	0.1023	4.7393
1.5% W-TiO ₂	0.1004	5.4885
0.0% Cu-TiO ₂	0.1039	4.4569
0.1% Cu-TiO ₂	0.1021	4.9759
0.5% Cu-TiO ₂	0.1010	4.4983
1.0% Cu-TiO ₂	0.1009	4.4389
5.0% Cu-TiO ₂	0.1002	5.2699
0.0% Mo-TiO ₂	0.1010	4.6309
0.1% Mo-TiO ₂	0.1020	3.8995
0.3% Mo-TiO ₂	0.1018	3.7916
0.5% Mo-TiO ₂	0.1009	3.8633
0.7% Mo-TiO ₂	0.1016	3.9885
1.0% Mo-TiO ₂	0.1011	4.1324

Example: Calculation of total acid sites.

1. Conversion of total peak area (see Table C.1) to peak volume;

Conversion from Micromeritics Chemisorb 2750 is equal 77.5016 mL/ unit area. Therefore, total peak volume is derived from

$$\begin{aligned} \text{Total peak volume} &= 77.5016 \times \text{total peak area} \\ &= 77.5016 \times 5.2705 \\ &= 397.9304 \text{ mL} \end{aligned}$$

2. Calculation for adsorbed volume of 15% NH₃;

$$\begin{aligned} \text{Adsorbed volume of 15\% NH}_3 &= 0.15 \times \text{total peak volume} \\ &= 0.15 \times 397.9304 \text{ mL} \\ &= 59.6896 \text{ mL} \end{aligned}$$

3. Calculation of total acid sites;

$$\text{Total acid sites} = \frac{(\text{adsorbed volume, ml}) \times 101.325 \text{ kPa}}{\left(8.314 \frac{\text{Pa} \cdot \text{ml}}{\text{K} \cdot \mu\text{mol}}\right) \times 298 \text{ K} \times (\text{weight of catalyst, g})}$$

For pure titania sample, 0.1026 g of this sample was measured, therefore

$$\begin{aligned} \text{Total acid sites} &= \frac{59.6896 \text{ mL} \times 101.325 \text{ kPa}}{\left(8.314 \frac{\text{Pa} \cdot \text{mL}}{\text{K} \cdot \mu\text{mol}}\right) \times 298 \text{ K} \times (0.1026 \text{ g})} \\ &= 23792.57 \mu\text{mol NH}_3/\text{g} \\ &= 23.79 \text{ mmol NH}_3/\text{g} \end{aligned}$$

APPENDIX D

CALCULATION OF OPTICAL BAND GAP ENERGY

In the visible region, the absorption coefficient (α) is influenced by the scattering of light on the surface roughness (being a transparent material in this domain, the light scattering dominates over the absorption), and it can be obtained from the approximate relation according to Equation D.1 (Mardare et al., 2000)

$$T = \frac{(1 - R)^2 \exp(-\alpha(\lambda)d)}{1 - R^2 \exp(-2\alpha(\lambda)d)} \quad (\text{D.1})$$

where T is the transmittance

R is the reflectance

d is the thickness of the film

λ is the wavelength

α is the absorption coefficient

However, at shorter wavelength close to the optical band gap, the scattering losses are dominated by the fundamental absorption and the following relation is often used according to Equation D.2 (Djaoued et al., 2007)

$$\alpha = -2.303 \frac{\log T}{d} \quad (\text{D.2})$$

Above the threshold of fundamental absorption near absorption edge, the dependence of α on incident light energy is known to obey the relation according to Equation D.3

$$\alpha h\nu = \alpha_0 (h\nu - E_g)^n \quad (\text{D.3})$$

$h\nu$ is the photon energy

α_0 is a constant which not depend on photo energy

E_g is optical band gap energy of film

n is characteristic value

The value of n may be taken $n = 2$, a characteristic value for the indirect allowed transition which dominates over the optical absorption (Mardare et al., 2000). Substitute Equation D.2 into D.3, so Equation D.4 can be became

$$(-2.303h\nu \log T)^{\frac{1}{2}} = B(h\nu - E_g) \quad (D.4)$$

where B is a constant. The graph of $(-2.303h\nu \log T)^{\frac{1}{2}}$ versus $h\nu$ will present a linear part that can be extrapolated to zero, leading to the band gap energy (E_g).

Example: Calculation of optical band gap energy of the films

Figure D.1 shows the graph of $(-2.303h\nu \log T)^{\frac{1}{2}}$ versus $h\nu$ of various W-TiO₂ films. After the linear part were extrapolated, the band gap energy were obtained and results were listed in Table D.1

APPENDIX E

CALCULATION OF THE CONTACT ANGLE

The contact angle of sample was calculated from height and radius of water droplet using trigonometry formula according to Equation E.1

$$\text{Contact angle} = 2 \arctan \frac{h}{r} \quad (\text{E.1})$$

where h is water droplet height
 r is water droplet radius
 2θ is contact angle

Figure E.1 The shape and dimension of water droplet on the surface.

VITA

Mr. Piyaphong Phromsalee was born on October 20, 1984 in Rayong province, Thailand. He received the Bachelor Degree of Chemical Engineering from Faculty of Engineering, Srinakharinwirot University, in 2007. He pursued his Master's study at Center of Excellence on Catalysis and Catalytic Reaction Engineering, Department of Chemical Engineering, Faculty of Engineering, Chulalongkorn University in June, 2007.
