

III EXPERIMENTAL PROCEDURE

The experimental part of this study was concerned with obtaining the load-deflection curves of bowed struts under a central lateral dead load. A testing apparatus was designed to accommodate as wide a range of testpieces as possible. A heavy steel frame was required capable of supporting both types of end fixing and the loading mechanism.

The specimen was set on the apparatus between two supporting brackets, one of which was bolted firmly on the heavy steel frame at a position corresponding to the length of the specimens, the other arranged to be move-able on the steel base plates which are also mounted on the steel frame. In order to obtain accurate results, air bearings with 100 psi air pressure were provided on the sliding bracket to minimize the friction between the move-able bracket (or sliding bracket) and the base plates. In the case of the hinged bowed strut the end supports can be easily rotated about the vertical axis on a pair of ball bearings which are mounted on each bracket, but for the clamped one the end supports can be locked to resist the rotation by the adjustable bolts as shown in Fig. 7.

To avoid any effect on the testing results due to the rigidity of the apparatus, a high factor of safety was used in the design of the apparatus to give a stiffness approximately 50 times that of the specimen based on the critical condition. At the end of the sliding bracket a 4-ton Capacity hydraulic ram mounted on the steel frame was provided for applying the compressive force to cause the initial

bowing and to resist the extension of the bowed strut during the application of lateral load. To ensure that the axial force was applied in the longitudinal direction, a steel ball was included at the end of the plunger of the ram. In order to investigate the mode shapes at various stages of loading, the three side gauges D1, D2 and D3 were mounted on the steel frame at $\frac{1}{4}$, $\frac{1}{2}$ and $\frac{3}{4}$ span of specimens respectively and two other gauges were provided at each end of the specimens for checking the span of bowed struts as shown in Fig. 7.

All the specimens were cut from a 2" wide and $\frac{1}{8}$ " thick mild steel bar. Generally the nominal length of the specimens was 48", the average width and thickness of each specimen being obtained from five measurements with micrometers.

After the specimen was set up and clamped between the end supports with socket screws, it was necessary to check the straightness of the specimen using a dial gauge sliding along the straight edge of the apparatus. Then the specimen was loaded by the hydraulic ram, worked by a manually-operated master pump, until the initial curvature corresponding to the given rise "b" of the bowed strut, measured by the central gauge D2, was obtained, i. e. the axial force applied by the ram, was slightly greater than the first Euler force. Now the readings of all gauges were recorded again. The lateral load was applied, in small increments at the mid span of the bowed strut through a wire rope passing over an adjustable pulley which was provided on both sides of the specimen. In order to be sure that the application of the lateral load was exactly

concentrated, a knife-edge bracket was used. The increments of lateral dead weight in pounds corresponding to the reading of all gauges were recorded in the data sheet, until the lateral dead weight was slightly greater than the critical load, the bowed strut became unstable and snap buckling took place. The span of the bowed strut at the initial state was kept constant throughout the test and it could be checked from the readings of end gauges DIV.1 and DIV.2.
